Abstract

The envelope (membrane) glycoprotein of HIV is essential for virus attachment and entry into host cells. Additionally, when expressed on the plasma membrane of infected cells, the envelope protein is responsible for mediating cell-cell fusion which leads to the formation of multinucleated giant cells, one of the major cytopathic effects of HIV infections. The envelope glycoproteins of HIV contain regions that can fold into amphipathic α -helices, and these regions have been suggested to play a role in subunit associations and in virus-induced cell fusion and cytopathic effects of HIV. We therefore tested the possibility that amphipathic helix-containing peptides and proteins may interfere with the HIV amphipathic peptides and inhibit those steps of HIV infection involving membrane fusion. Apolipoprotein A-I, the major protein component of high density lipoprotein, and its amphipathic peptide analogue were found to inhibit cell fusion, both in HIV-1-infected T cells and in recombinant vaccinia-virus-infected CD4⁺ HeLa cells expressing HIV envelope protein on their surfaces. The amphipathic peptides inhibited the infectivity of HIV-1. The inhibitory effects were manifest when the virus, but not cells, was pretreated with the peptides. Also, a reduction in HIV-induced cell killing was observed when virus-infected cell cultures were maintained in presence of amphipathic peptides. These results have potential implications for HIV biology and therapy. (*J. Clin. Invest.* 1990. 86:1142–1150.) Key words: HIV • apolipoprotein • HDL • amphipathic helix • antiviral activity

Introduction

The human immunodeficiency virus is widely accepted as being the etiologic agent responsible for AIDS. The HIV envelope (membrane) glycoprotein is synthesized first as a polypeptide, gp160; it then is cleaved intracellularly to give rise to a gp120-gp41 complex and transported to the plasma membrane (1–4). This cleavage event has been shown to be necessary for viral infectivity and for the formation of multinucleated syncytia by cell-cell fusion, the major cytopathic effect of HIV infections (5). After cleavage, a new hydrophobic amino terminus is exposed on gp41 that is important for mediating fusion of the viral envelope with a cellular membrane, leading

to release of the viral nucleocapsid into the cytosol (6, 7). The process of virus-induced cell fusion is thought to be analogous to the process involved in fusion of viral membranes with cell membranes and interruption of this process has been shown to reduce viral replication and syncytium formation in a number of virus systems (8–13). In model membrane systems, certain agents that stabilize the membrane bilayer have been shown to inhibit membrane fusion (14, 15).

Amphipathic α -helices were initially described in the structures of myoglobin and hemoglobin (16), and contain opposing polar and nonpolar faces, which are readily visualized in “helical wheel” diagrams showing the asymmetric distribution of nonpolar and polar residues along the axis of the helix (17). The amphipathic helical structures have been identified in a variety of proteins, particularly apolipoproteins, and may account for their strong affinity for phospholipids (18). This hypothesis has been supported by structure-function studies with synthetic peptide analogs (19–25). Examples of other amphipathic helix-containing proteins include certain lipid-associating polypeptide hormones (for example, β -endorphin and calcitonin) (26), novel antimicrobial agents, such as magainins (27), cecropins (28), as well as type I and type II (IFN- γ) interferons (29). Recently, several reports have indicated the presence of potential amphipathic helical domains in the HIV envelope glycoprotein. Two potentially amphipathic helical domains that display a high mean hydrophobic moment within the carboxy terminus of gp160 have been predicted by computer modeling; one is located 70 residues from the carboxy terminus between amino acids 768–788 and the other directly at the carboxy terminus between amino acids 826–854 (30). There are additional regions in gp120 and gp41 that can form amphipathic helical domains, some of which are conserved in different isolates of HIV-1, HIV-2, and Simian immunodeficiency virus, and these regions are thought to be involved in gp120-gp41 subunit interactions (31). Studies on the topology of HIV-1 gp160 in membranes have shown that the carboxy terminus is inaccessible to proteases or sequence specific antibodies, and indicate that the carboxy terminus of gp41 may be associated with the membrane bilayer (32). The peptide analogues of these helices have been suggested to mediate fusion of lipid vesicles (30). Although mutational analyses of the carboxy-terminal region of the gp41 subunit include conflicting data from different laboratories, they nevertheless suggest that the carboxy terminus of gp41 may be required for viral cytopathology (33, 34). Like apo A-I amphipathic peptides, the gp41 carboxy-terminal amphipathic peptides also contain positively charged residues at the polar-nonpolar interface, although the polar faces of gp41 amphipathic peptides are significantly more basic. In contrast to apo A-I amphipathic peptides, synthetic peptides corresponding to gp41 amphipathic peptides were found to be lytic, and toxic to cells (unpublished observations).

Because of the marked bilayer affinity of amphipathic helical peptides of the apolipoprotein type, their similarity to gp41 carboxy-terminal amphipathic peptides and lack of cytotoxicity, we investigated the possibility that these structures might inhibit HIV-induced membrane fusion. A number of amphipathic peptide analogues of apo A-I with a wide spectrum of affinities for phospholipid bilayers have been synthesized and characterized (19, 23). Four peptide mimics of apo A-I, the major protein of HDL, with amphipathic helical structures and differing lipid affinities were studied for their effects on cell fusion. We have also investigated the effects of these peptides upon HIV infectivity and the viability of HIV-infected cells.

Methods

HDL, apo A-I, and synthetic amphipathic peptide analogues. HDL and apo A-I were prepared according to previously described procedures and purified by HPLC (35). The peptides were synthesized by a solid-phase method in which benzyl-based protecting groups were used for side chain protection, and released from the resins as described earlier (19). The peptide synthesis was carried out using an automated peptide synthesizer (Advanced Chemtech, Inc., Louisville, KY). All the peptides were purified by HPLC, and purity was verified by thin-layer chromatographic analysis, amino acid analysis, and sequencing. The peptides used include: (a) 18A, an 18-residue-long peptide capable of forming an amphipathic helix, which contains positively charged arginine residues at the polar-nonpolar interface; (b) 37aA, a dimer of 18A linked via an alanine residue (18A-ala-18A); (c) 37pA, a dimer of 18A connected via a proline residue (18A-pro-18A); (d) 18R, in which positions of the charged residues are exchanged so that resulting helix contains negative charges at the polar-nonpolar interface of the helix; and (e) 18S, in which the residues in 18A were scrambled so that they did not form any amphipathic helix. The primary sequence and helical wheel representation of these peptides is shown in Fig. 1.

Cells and viruses. Vero cells (clone 76; American Type Culture Collection, Rockville, MD), and CD4+ HeLa cells (6) were maintained in DMEM supplemented with 5% newborn calf serum. Uninfected Sup T1 cells, MT-2 cells (36), and H9 cells persistently infected with HIV-III_B were maintained in RPMI supplemented with glutamine and 10% fetal calf serum. The HTLV-III_B strain of HIV-1 was obtained from Dr. Beatrice Hahn (University of Alabama at Birmingham [UAB]), and maintained by serial passage in H9 or MT-2 cells. Poliovirus type 1 (Mahoney) was obtained from Dr. Casey Morrow (UAB), and maintained by serial passage in HeLa cells. A recombinant vaccinia virus (VV),¹ VVenv1, which expresses the HIV-1 envelope protein, was described previously (37). A recombinant vaccinia virus (rVV) expressing the HIV-2 (ROD), envelope protein, VV-HIV2(ROD), was kindly supplied by Dr. Mark Mulligan (UAB).

Cell fusion assays. Fusion assays with HIV were carried out using either CD4+ HeLa cell monolayers or suspension cultures of human T lymphocytic cell lines. CD4+ HeLa cells were grown as monolayers in sterile 96-well tissue culture plates. Confluent monolayers were infected with rVV at a multiplicity of 0.05 plaque forming unit (pfu) per cell. The virus was allowed to adsorb for 1 h at 37°C. The inoculum was removed and replaced with DMEM containing various concentrations of the peptides, apo A-I or HDL. The cells were incubated for 17 h at 37°C. The monolayers were fixed with ethanol-acetic acid (95:5), stained with Wright-Giemsa stain, and examined microscopically for cell fusion. The area involved in fusion was determined using a Bioquant digitizer (Nashville, TN). In a second set of experiments,

1. Abbreviations used in this paper: HSV, herpes simplex virus; moi, multiplicity of infection; MTT, 3' (4,5-dimethyl thiazole-2-yl)-2,5-diphenyl tetrazolium bromide; pfu, plaque-forming unit; rVV, recombinant VV; VV, vaccinia virus.

Figure 1. Structure of amphipathic peptide analogue of apo A-I. Peptides 18A, 18R, and 18S are depicted as helical wheels with a view along the axis of the α -helix beginning at the amino terminus. Peptides 37aA and 37pA are dimers of 18A covalently linked by either alanine or proline.

uninfected Sup T1 cells were co-cultivated with H9 cells persistently infected with HIV-1 (HTLV-III_B) in 96-well plates at a ratio of 10:1 and incubated in the presence of various concentrations of peptides dissolved in RPMI medium. After 24 h of infection, the numbers of multinucleate giant cells were determined by microscopy.

Envelope protein synthesis and processing. Monolayers of CD4+ HeLa cells were grown to confluency in 24-well cluster plates in DMEM supplemented with 5% NCS. Cells were infected at a multiplicity of infection (moi) of 1 with either VVenv1 or wild-type vaccinia virus (IHD-J strain) and after a 1-h adsorption period, the supernatant was removed and replaced with 400 μ l of each peptide dissolved in DMEM. At 8 h postinfection the cells were metabolically labeled with [³⁵S]methionine for 2 h and lysed in 0.5 ml lysis buffer (50 mM Tris-HCl pH 7.5, 0.15 M NaCl, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, and 20 mM EDTA). The lysates were immunoprecipitated using HIV immune globulins (obtained through the AIDS Research and Reference Reagent Program, AIDS Program, National Institute of Allergies and Infectious Diseases, National Institutes of Health, ERC Bioservices Corporation, MD) and protein-A Sepharose according to previously described procedures (37).

Surface expression of envelope proteins. Monolayers of CD4+ HeLa cells were grown on 12-mm glass coverslips in 24-well cluster plates in DMEM supplemented with 5% NCS. Cells were infected at an moi of 0.1, and treated with peptide solutions as described above. At 10 h postinfection, intact unfixed monolayers were examined by indirect

immunofluorescence assay using HIV immunoglobulin and FITC-conjugated goat anti-human Ig (Southern Biotechnology, Inc., Birmingham, AL) as described previously (37).

Effect of amphipathic peptides on HIV-1 infection of MT-2 cells. The amphipathic peptides 37pA and 37aA were used at a concentration of 25 μ M or 50 μ M. MT-2 cells were pretreated with the peptides for a period of 60 min at 37°C and infected with HIV-1 (HTLV-III_B) at a multiplicity of 0.03. In a second set of experiments, an inoculum adjusted to provide a multiplicity of 0.03 pfu/cell was preincubated with the peptides for 30 min at 37°C and used to infect MT-2 cells. Controls included untreated, uninfected cultures, and untreated, infected cultures. All the cultures were incubated for a period of 48 h and the cells from replicate cultures were pooled, washed three times with PBS, and solubilized in guanidine isothiocyanate buffer. 10- μ l aliquots were blotted onto nitrocellulose filters using a dot-blot apparatus, and hybridized to a ³²P-labeled HIV-1 pol gene-specific probe (Genetrack Systems, Framingham, MA) according to standard procedures (38).

Effect of amphipathic peptides on the viability of HIV-infected MT-2 cells. Actively growing cultures of MT-2 cells were pelleted and resuspended in growth medium at a density of 2×10^5 cells/ml. The cells were infected with HIV-1 (strain HTLV-III_B) at a multiplicity of 0.03 or 0.003. After a 2 h incubation at 37°C, unadsorbed virus was removed by washing. The cells were resuspended at a density of 2×10^5 cells/ml and 100- μ l aliquots were dispensed into 96-well microtiter plates. An equal volume of RPMI medium containing the amphipathic peptides 37pA or 37aA was added to duplicate sets of cultures. Control cultures included uninfected cultures with or without amphipathic peptides 37aA and 37pA, and infected cultures without any amphipathic peptides. All the cultures were maintained at 37°C in a CO₂ incubator. After a 3 d culture, the test compounds were replenished by addition of 10- μ l aliquots of a 20 \times concentrated solution of appropriate peptides. The cultures were incubated for a further 3 d and the percentage of viable cells was determined by adding 3' (4,5-dimethyl thiazole-2-yl)-2,5-di-phenyl tetrazolium bromide (MTT) to the test plates. MTT is taken up by viable cells and converted into a colored formazan derivative. The formazan derivative was solubilized by the addition of 10% SDS in 0.01 N HCl, and the color intensity was measured by determining the optical density using an ELISA plate reader. The optical density value is a function of the amount of formazan produced, which is proportional to the number of viable cells.

Results

Peptide 18A is a model amphipathic α -helix that has been shown to mimic apo A-I in many of its interactions with phos-

pholipid. Reversal of the location of the positively and negatively charged residues, so that the basic amino acid residues are no longer at the polar-nonpolar interface, produced a peptide, 18R, with greatly reduced lipid affinity. Peptides 37aA and 37pA are dimers of 18A linked by either an alanine or proline residue, respectively, and have also been shown to have high lipid affinity (19, 23). In contrast, 18S, which failed to form an amphipathic helix did not show any lipid affinity (data not shown).

To investigate the inhibitory activities of peptides on HIV-induced cell fusion, we used CD4⁺ HeLa cells infected with the VVenv1 recombinant virus. Cells were infected with VVenv1 at a multiplicity of 0.05, and allowed to adsorb for 2 h. The virus inoculum was removed and the cells were maintained for 24 h in DMEM with or without peptides, and analyzed for syncytium formation. The results were quantified by measuring the area of the cell monolayer involved in syncytium formation in peptide-treated samples and untreated controls and expressed as a function of concentration (Table I, Fig. 2). The peptides 18A, 18R, 37aA, and 37pA were found to inhibit virus-induced cell fusion. The inhibitory effects of all the peptides were found to be dose dependent, with nearly 100% inhibition occurring at a concentration of 100 μ M for peptides 18A, 37aA, and 37pA. In contrast, very little inhibition was observed with peptide 18R at similar concentrations. The peptide 18S, which does not form an amphipathic helix, did not show any inhibitory activity. These results demonstrate that synthetic amphipathic peptide analogues of apo A-I inhibit HIV-induced syncytium formation at relatively low concentrations. The four amphipathic peptides were also effective in inhibiting cell fusion induced by rVV-HIV-2(ROD), which is distinct from HIV-1 in its amino acid sequence, demonstrating that the inhibitory effects of the peptides are not confined to specific strains of HIV-1.

In order to determine whether these peptides were inhibiting envelope protein synthesis or processing, VVenv1-infected cells were radiolabeled in the presence or absence of the peptides, and viral proteins analyzed by immunoprecipitation and SDS-PAGE (Fig. 3 a). The level of envelope protein synthesis and processing was found to be indistinguishable in peptide-treated and untreated cells. In addition, we analyzed the ex-

The area of monolayer involved in cell fusion was determined using a digitizer as described in Methods, and the results were expressed as percentage of area involved in fusion in cultures without any peptides. The average area involved in fusion was 25% of the monolayer in control cultures. * Each figure represents a mean of three separate experiments.

a**b**

Figure 2. Inhibition of HIV-induced syncytium formation by amphipathic helical peptides. CD4⁺ HeLa cells were infected with recombinant vaccinia virus (VVenv1) (A, C, and D) or wild type vaccinia virus (IHD-J strain) (B). Cells in C were treated with 100 μ M of peptide 18A, and in D, with 100 μ M of peptide 18R.

pression of the envelope protein on the cell surface by immunofluorescence, and no differences in surface expression were detected in peptide-treated cells and untreated controls (Fig. 3 b). These results suggest that the inhibitory effects of the peptides are exerted directly upon the fusion process.

To determine whether the amphipathic peptides were also capable of inhibiting syncytium formation in HIV-infected T cells, the helper T cell line Sup T1 was co-cultivated with H9 cells persistently infected with HIV-III_B in the presence of various concentrations of each peptide, and scored for syncytium formation 18 h later. As found with the VVenv1 recombinant, marked inhibition of syncytium formation was observed with peptides 18A, 37aA, and 37pA, while inhibition by 18R was negligible. Table II summarizes the results from both recombinant vaccinia-virus-infected cells and HIV-1-infected cells and compares the ID₅₀ (concentration required for 50% syncytium inhibition) for all of the peptides tested.

Because the amphipathic peptide analogues of apo A-I were found to be effective inhibitors of cell fusion, we also analyzed the inhibitory activity of the parent apo A-I molecule. CD4⁺ HeLa cells were infected with the VVenv1 recombinant at an moi of 0.05 and incubated with various concen-

trations of apo A-I. 54% inhibition was observed at a concentration of 4 μ M, reaching a maximum of 67% inhibition at 8 μ M. However, when the cells were exposed to higher concentrations of apo A-I, they were observed to round up and become detached from the culture plates.

The process involved in cell-to-cell fusion is thought to be analogous to the processes involved in fusion of viral membrane to the cell membrane during virus penetration (39). We therefore investigated the effects of amphipathic peptides 37aA and 37pA on HIV-1 (HTLV-III_B) infection in MT-2 cells (see Methods). The effect on virus replication was monitored by assaying for virus-specific RNA in the cells' lysates at 48 h postinfection by dot-blot hybridization using a HIV-1 *pol* gene-specific probe (Fig. 4). Cell lysates from untreated, virus-infected controls yielded a strong signal, nearly twice as intense as the 1-ng virus standard. No nonspecific hybridization was observed in uninfected cells. A significant decrease in virus-specific RNA levels was observed in cells infected with virus pretreated with either 37aA or 37pA. The inhibition was found to be dose dependent, and was observed at 50 μ M (but not 25 μ M) concentrations of the peptides. In contrast, no significant reduction in HIV-1 replication was observed in

MT-2 cells pretreated with either of the peptides (Fig. 4). Together, these results indicate that the peptides may interact with some component of HIV virions and lead to an inactivation of virus infectivity.

To determine the effects of peptide treatment on HIV-infected cell cultures, we monitored the viability of HIV-1-infected MT-2 cultures ($\text{moi} = 0.03$ or 0.003), maintained in the presence or absence of the amphipathic peptides 37pA or 37aA by a colorimetric assay based on uptake of chromogenic substrate MTT. The results are summarized in Table III. Over a 6-d period, the number of viable cells in cultures infected with HIV-1 at a multiplicity of 0.03 was 30% of the total viable cells in uninfected controls. No detectable increase in the number of viable cells was observed with the peptide 37aA at concentration of $25 \mu\text{M}$. However, the percentage of viable cells increased to 36% in cultures maintained at $50 \mu\text{M}$ 37aA or $25 \mu\text{M}$ 37pA, and to 46% in cultures maintained at $50 \mu\text{M}$ 37pA, thus demonstrating an increase in the number of viable cells in peptide-treated cultures. This increase was more readily observed in cultures infected at a lower multiplicity. The number of viable cells in untreated, HIV-1-infected (0.003 pfu/cell) cultures was 40% of the total viable cells in uninfected controls. The viable cell numbers were 61% and 68% , respectively, in cultures treated with $50 \mu\text{M}$ 37aA or 37pA, as compared to 40% in untreated cultures. Cell killing in HIV-infected cultures has been attributed to syncytium formation, as well as single-cell killing of virus-infected cells. Possibilities which may account for the observed increase in the number of viable cells in peptide-treated cultures include: (a) an inhibition in syncytium formation which is thought to be responsible for killing uninfected CD4^+ cells; (b) a reduction in the infectivity of progeny virus, thus leading to a reduction in the number of secondarily infected cells; or (c) a direct effect on the viability of HIV-infected cells. Further studies are required to identify which of these factors may account for increased viability in peptide-treated, HIV-infected cultures.

In order to determine whether the apo A-I and its amphipathic peptide analogues inhibit other fusogenic, enveloped viruses, we investigated their effects on herpes simplex virus (HSV-1). Apo A-I was found to inhibit HSV-1, MP-induced cell fusion at physiological ($\sim 1 \mu\text{M}$) concentrations. The peptides 18A, 37aA, and 37pA also inhibited HSV-induced cell fusion and the ID_{100} values were 2 , 4 , and $2 \mu\text{M}$, respectively. In contrast, the peptide 18R, in which the distribution of charged residues was reversed, inhibited virus-induced cell fusion only at a much higher ($\sim 125 \mu\text{M}$) concentration. Consistent with their ability to inhibit virus-induced cell fusion, the peptides inhibited the spread of HSV infection as demonstrated by a 10-fold reduction in the yields of both highly fusogenic strain MP, and the wild-type McIntyre strain of HSV, when virus-infected cells were maintained in the presence of amphipathic peptides. The amphipathic peptides also inhibited penetration of HSV into cells. A nearly complete inhibition of virus penetration was observed when the virus, or both virus and cells, was pretreated with the peptide, suggesting that the peptides may have a direct effect on the virus. A detailed description of these results are presented elsewhere (40).

In order to further study the specificity of the inhibitory effects of amphipathic peptides, we investigated their effects on the replication of nonenveloped poliovirus. Cells infected with poliovirus (10 TCID_{50}) were maintained in the presence or

Figure 3

absence of serial twofold dilutions of the peptides 18A and 18R, and observed for poliovirus-induced cytopathology 24 h after infection. Cells pretreated with the peptides for 24 h were also infected with 10 TCID_{50} dose of poliovirus to determine whether peptide treatment inhibits the binding or entry of the virus. In another experiment, the cells were pretreated with the peptide, and peptide treatment was maintained both during adsorption and throughout the infection period. No inhibition of poliovirus infection was observed in any of these experiments at peptide concentrations as high as $500 \mu\text{M}$. These results indicate that the inhibitory effect of amphipathic peptides is specific for enveloped viruses.

The amphipathic peptides may be regarded as peptide detergents. In an attempt to determine whether the fusion-inhibitory properties of the peptides are related to their detergent-like properties, we also investigated the fusion-inhibitory properties of a known detergent, sodium desoxycholate (DOC). Uninfected or VVenv1-infected HeLa T4 cells were maintained in the presence of varying concentrations of DOC and examined for cell viability and fusion. DOC at concentrations above $125 \mu\text{M}$ was toxic to the cells. However, there was $\sim 50\%$ inhibition in VVenv1-induced cell fusion at a concentration of $62.5 \mu\text{M}$ DOC. Thus, unlike amphipathic peptides, the inhibitory concentration of the detergent was very close to its toxicity limit.

Discussion

We have demonstrated that apo A-I and its synthetic, amphipathic α -helical peptide analogues are effective inhibitors of HIV-induced syncytium formation. A feature of the most ef-

b

Figure 3. Envelope protein synthesis and transport in the presence of inhibitory peptides. (a) Immunoprecipitation of envelope proteins. Lane 1, wild-type vaccinia-infected cells; lanes 2–7, VVenv1-infected cells; lane 2, no peptide; lane 3 100 μ M 18A; lane 4, 100 μ M 18R; lane 5, 100 μ M 37aA; lane 6, 100 μ M 37pA; and lane 7, 8 μ M apo A-I. Peptide treatment had no effect on the level of protein synthesis or processing of the gp160 precursor as compared to the untreated control. (b) Surface expression of envelope proteins. A, C–F, VVenv1-infected cells; B, wild-type vaccinia control. A, no peptide; C, 100 μ M 18A; D, 100 μ M 18R; E, 100 μ M 37aA; and F, 100 μ M 37pA. Relative levels of fluorescence were the same in peptide-treated samples as in the untreated control, indicating that the peptides were not blocking transport of the envelope protein to the cell surface.

fective inhibitors seems to be the positioning of basic amino acid residues at the polar–nonpolar interface of the amphipathic helix. When the positions of basic and acidic residues were exchanged on the polar surface (in the case of peptide 18R), inhibitory activity was greatly reduced. The reason for this is not immediately clear; however, the hydrophobic portion of the lysine and arginine side chains clustering at the polar–nonpolar interface could allow the amphipathic helix to bury itself deeper in the lipid bilayer or increase its affinity for hydrophobic protein domains, such as the fusion domain at the NH₂ terminus of gp41.

We have previously shown that the three peptides 18A, 18R, and 37pA have a relative lipid affinity of 37pA > 18A > 18R (19). While 18R with the lowest lipid affinity was least effective in inhibiting virus-induced cell fusion, 18A was just as active as 37pA in inhibiting virus-induced cell fusion. Thus there appears to be no absolute correlation between lipid affinity of the amphipathic peptides and their ability to inhibit virus-induced cell fusion, suggesting that the inhibition of

virus-induced cell fusion mediated by the peptides may not be mediated merely by the lipid binding of these peptides. Consistent with their ability to inhibit cell fusion, the amphipathic

Figure 4. Effect of amphipathic peptides on HIV-1 infections in MT-2 cells. Total cellular RNA isolated from peptide-treated or untreated MT-2 cell cultures infected with untreated or peptide-treated HIV-1 (moi = 0.03) were subjected to Northern, dot-blot analyses using a ^{32}P -labeled HIV-1 pol gene-specific probe, according to the

procedures described under Methods. Purified HIV-1, and RNA from untreated MT-2 cells infected with untreated HIV-1 were used as positive controls. Preincubation of virus with either 37aA or 37pA was found to inhibit HIV-1 infectivity in a dose-dependent manner, while no significant reduction in HIV infectivity was observed when cells were preincubated with the peptides.

peptides also inhibited HIV infectivity, when the virus was pretreated with the peptides.

The exact mechanism by which apo A-I and its peptide analogues exert their inhibitory effects is not known; however, several possibilities are outlined in Fig. 5. One possibility is that the amphipathic peptides may perturb the lipid bilayer organization of either the viral membrane, or the cell membrane, or both, and alter its fusogenic properties. Perhaps inhibition is related in some way to the presence of putative amphipathic helices in gp120 and gp41. If amphipathic domains are involved in gp120-gp41 subunit interactions, the apo A-I amphipathic peptides may disrupt this association, leading to a loss of gp120 from viral (and cell) membranes. Alternatively, if the carboxy-terminal gp41 amphipathic domains play some role in mediating virus entry and cell fusion, the apo A-I amphipathic peptides may interact with these domains and disrupt their normal function. Also, the nonpolar surface of the amphipathic helix could be associating with the fusogenic domain of gp41, thereby preventing it from interacting with a target membrane. Pretreatment of CD4⁺ cells with the peptides failed to inhibit HIV infection. It is therefore unlikely that these compounds bind to a putative "fusion receptor" and block its interaction with the fusogenic domain of the envelope protein, or with the binding of gp120 to the CD4 receptor.

Table III. Viability of HIV-I (HTLV-III_B) Infected MT-2 Cells Maintained in Presence of Amphipathic Peptides

Treatment	% Viability in cultures infected at	
	0.03 moi	0.003 moi
Uninfected	100*	100
Infected, no peptide	30	40
Infected, 37aA (25 μM)	30	40
Infected, 37aA (50 μM)	36	61
Infected, 37pA (25 μM)	36	48
Infected, 37pA (50 μM)	46	68

The optical density of the formazan derivative was used as a measure of total number of viable cells in the culture. The results are expressed as percentage of viable cells, as compared to values obtained with uninfected controls.

* Figures indicate percent viability as determined by a colorimetric assay based on uptake and conversion of a chromogenic substrate MTT by viable cells.

Experiments are currently underway to determine the site of action for apo A-I and its analogues.

Apo A-I is the major protein component of HDL. High plasma levels of HDL have been found to be a common and perhaps hereditary factor for long-lived individuals; not all of this longevity can be accounted for by protection from coronary artery disease (41). While hypertriglyceridemia has been reported to be a common finding in AIDS (42), to our knowledge there have been no studies that address whether low plasma levels of HDL are associated with HIV infection. In a retrospective study of 35 male HIV seropositive subjects compared with healthy controls, we found a significant reduction in mean HDL cholesterol levels in previously frozen serum

Figure 5. Model of possible sites of inhibition of HIV-induced membrane fusion by the amphipathic helix. (A) Membrane fusion in the absence of peptide treatment. The first step requires an interaction between gp120 and the CD4 receptor, to bring the two membranes into close proximity. Then, gp41 probably perturbs the membrane bilayers (by an unknown mechanism) resulting in fusion of the two membranes. (B) The amphipathic helix could be acting at one or a combination of the above sites: 1a and/or 1b, perturbation of the lipid bilayer; 2, interaction with the fusogenic domain in gp41; 3, interaction with a specific fusion receptor (Fr); or 4, interfering with gp120-CD4 binding.

samples from patients with frank AIDS, or AIDS-related complex (ARC), as well as in asymptomatic individuals. In order to rule out the possibility of artifactual HDL lowering secondary to freeze-thaw damage, three separate control studies were performed. In these studies, control sera were subjected to identical storage conditions (freezing and thawing) as the sera from HIV positive patients. Unfortunately, the results of the three studies have given conflicting results, thus leaving open the question of an association of low HDL levels with HIV infectivity. Additionally, the question of low HDL being the consequence of HIV infectivity, as opposed to being a preexisting risk factor, cannot be resolved without prospective study of plasma HDL levels in individuals at high risk for development of infection. Nevertheless, no matter what the role of HDL as a possible risk factor for HIV infection, it is important to consider synthetic amphipathic peptides themselves as potential therapeutic agents.

Acknowledgments

We thank Kiran Gupta, Cris McGee, and Cynthia Tanner for excellent technical assistance, and Eugene Arms for photography.

This study was supported by grants HL-34343, CA-40440, AI-25784 from the National Institutes of Health and the Center for AIDS Research, Birmingham. Dr. Owens was supported in part by Institutional Research Service Award AI-07150 from the National Institutes of Health.
