Abstract

Fibrosis results when myofibroblasts invade the wound fibrin provisional matrix. Extracellular matrix receptors on the cell surface mediate cell adhesion, migration, and invasion. Recent work with transformed cells indicates that these cells use the cell surface matrix receptor CD44 for migration and invasion. In this study, we examine whether lung fibroblasts, isolated from patients dying with acute alveolar fibrosis, use CD44 to invade a fibrin matrix. Consistent with a role for CD44 in mediating fibroblast invasion and subsequent tissue fibrosis, immunohistochemical analysis of lung tissue from patients who died from acute alveolar fibrosis after lung injury reveals CD44-expressing mesenchymal cells throughout newly formed fibrinous tissue. PCR, Western, and immunoprecipitation analysis demonstrate that the 85-kD CD44 isoform is expressed by acute lung injury fibroblasts. Consistent with a role in mediating matrix adhesion and migration ultrastructurally, CD44 was found uniformly over the cell surface and was found densely labeling filopodia and lamellipodia, highly motile structures involved in cell migration. To determine if lung injury fibroblasts use CD44 to invade fibrin, a fibrin gel model of fibrosis was used. By blocking the function of CD44 with monoclonal antibodies, fibroblast invasion into a fibrin matrix was inhibited. To examine the mechanism by which CD44 mediates fibroblast invasion, the role of CD44 in fibroblast migration and adhesion was evaluated. Anti–CD44 antibody blocked fibroblast migration on the provisional matrix proteins fibronectin, fibrinogen, and hyaluronic acid. Additionally, fibroblast CD44 mediated adhesion to the provisional matrix proteins fibronectin, fibrin, and hyaluronic acid, but not to laminin, a component of the basement membrane. These findings support the hypothesis that fibroblast CD44 functions as an adhesion receptor for provisional matrix proteins and is capable of mediating fibroblast migration and invasion of the wound provisional matrix resulting in the formation of fibrotic tissue. (J. Clin. Invest. 1996, 98:1713–1727.) Key words: lung fibrosis • airspace provisional matrix • fibroblast migration • CD44 • apoptosis

Introduction

The biological process of fibrosis occurs in response to various stimuli in many biological systems. During some repair processes, such as cutaneous wound healing, fibrosis functions as a necessary homeostatic mechanism. In other cases, however, fibrosis may occur at critical anatomic sites, thereby adversely affecting organ function.

One example of pathological fibrosis is pulmonary alveolar fibrosis after acute lung injury. The pathophysiological process characteristic of acute lung injury begins with an inflammatory insult to the alveolar wall. As a result, plasma-derived fluid flows through the disrupted alveolar wall and into the airspaces where plasma fibrinogen becomes clotted to cross-linked fibrin, entrapping plasma proteins such as fibronec-tin in solid phase (1). In response to migration and growth-promoting signals present within the fibrin provisional matrix, myofibroblasts and endothelial cells invade the airspace, divide, and form intraalveolar granulation tissue (2, 3). This can lead to obliteration of the gas exchange apparatus with fibrinous tissue and subsequent respiratory insufficiency.

The molecular basis for fibroblast migration and invasion into the fibrin matrix during wound and tissue repair is not fully understood. In general, cells adhere and migrate on extracellular matrix components via cell surface matrix receptors that bind distinct domains on extracellular matrix proteins. One such receptor, RHAMM, has been implicated in facilitating fibroblast migration on hyaluronan (4). Studies examining the molecular basis of tumor cell migration and invasion have identified another surface receptor, chondroitin sulfate proteoglycan (CSPG), containing CD44 as its core protein, as important in tumor cell migration and invasion. In studies of melanoma cells, CD44-related CSPG has been shown to play a role in mediating melanoma cell invasion of type I collagen gels (5). Furthermore, studies on tumor cells linking the transmembrane glycoprotein CD44 with cell motility demonstrate that the expression of specific splice variants of CD44 correlate with metastatic potential in model systems of rat pancreatic carcinoma (6, 7). In addition, overexpression of CD44 cDNA in tumor cells has correlated with increased cell motility, enhanced tumor growth, and metastatic proclivity in nude mice (8, 9).

Several lines of evidence link CD44 with fibroblast adhesion and migration and the development of fibrosis. First, CD44 is a cell surface matrix receptor for several extracellular matrix components including hyaluronic acid and fibronectin (10, 11). Second, elevated levels of fibronectin and hyaluronic acid accumulate in the fibrin provisional matrix and have been

Volume 98, Number 8, October 1996, 1713–1727
recovered from the air–lung interface after the onset of acute lung injury (12–15). Importantly, fibronectin, fibrin, and hyaluronic support cell motility (16–19). Third, cell surface CD44 expression has been found to be increased in hypertrophic scar fibroblasts derived from human cutaneous scar tissue as compared to normal skin fibroblasts (20). Collectively, these data suggest that CD44 may be an important cell surface adhesion receptor capable of mediating fibroblast migration and invasion into the wound provisional matrix during tissue repair. However, no data exists that directly identifies this cell surface matrix receptor with fibroblast invasion, either ex vivo or in vivo. Our objective in the present study was to develop such data.

To determine if CD44 is an important matrix receptor capable of mediating fibroblast migration and invasion into the fibrin provisional matrix during tissue repair, we have examined fibroblasts isolated from patients dying from the fibroproliferative disorder of acute alveolar fibrosis after lung injury. Immunohistochemical analysis of lung tissue derived from patients with acute lung injury revealed CD44-expressing mesenchymal cells throughout newly formed fibrotic tissue in the injured lung. PCR, Western, and immunoprecipitation analysis demonstrated that acute lung injury fibroblasts express the 85-kD isoform of CD44. Consistent with a role in adhesion and migration ultrastructurally, CD44 was found on filopodia and lamellipodia and could be found at the leading edge of migrating fibroblasts. By blocking CD44 function with an anti–CD44 antibody, acute lung injury fibroblast adhesion and migration on fibronectin, fibrinogen, hyaluronic acid, and invasion into fibrin gels was inhibited. Collectively, these results are consistent with the hypothesis that CD44 is a cell surface matrix adhesion receptor involved in mediating fibroblast invasion of the fibrin provisional matrix during tissue repair.

Method

Source of lung mesenchymal cells

Five primary cultures of lung mesenchymal cells were developed from the lungs of patients with severe acute lung injury (adult respiratory distress syndrome) as previously described (21):

Source of tissue for histological analysis and isolation of lung mesenchymal cells (n = 5). This group consisted of lungs from patients who died from respiratory failure 14, 21, and 30 d after disease onset and who met established criteria for the adult respiratory distress syndrome (22, 23). Histological analysis of each lung specimen revealed diffuse alveolar damage and intraalveolar fibrosis.

Additional source of lung mesenchymal cells (n = 2). Primary mesenchymal cell cultures were developed from an additional two patients with severe acute lung injury being supported with mechanical ventilation who met the standard criteria for adult respiratory distress syndrome. Patients in this cohort underwent bronchoscopy with bronchoalveolar lavage for purposes of obtaining mesenchymal cells from the alveolar air–lung interface. These patients had bronchoalveolar lavage performed 14–28 d after disease onset, which correlates with the fibroproliferative phase of adult respiratory distress syndrome.

Source of normal fibroblasts

One diploid fibroblast strain, normal lung fibroblasts (210; American Type Culture Collection, Rockville, MD) was also used. Cell cultures were stored frozen until ready for use. The normal lung fibroblasts were maintained in culture (37°C, 10% CO2) in DMEM containing 10% heat-inactivated fetal calf serum, subcultivated weekly and used before the eighth subcultivation. Normal lung fibroblasts in culture were used for subsequent experiments at 50–75% of their saturation density unless otherwise specified.

Preparation of mesenchymal cell cultures

Mesenchymal cell primary cultures were developed from the lungs of patients who died from respiratory failure after onset of lung injury by enzymatic and mechanical dispersion of lung tissue in a manner designed to optimize viability and yield as previously described (n = 3) (21). Cultures were stored frozen until ready for use and subcultivation was performed weekly. Lung injury cells were used for subsequent experiments at 50–75% of their saturation density unless otherwise specified, and before the 12th subcultivation.

Primary cultures of airspace mesenchymal cells were isolated from bronchoalveolar lavage fluid (n = 2). Briefly, the lavage fluid was centrifuged (10 min, 1,300 g, 20°C), resuspended in DMEM with 10% heat-inactivated fetal calf serum, and plated on 100-mm tissue culture dishes (Falcon 3003; Becton Dickinson Labware, Lincoln Park, NJ). These cells were refed three times a week and first passaged after several confluent colonies larger than a high power field were observed. Cultures were stored frozen until ready for use and subcultivation was then performed weekly. Airspace lung injury mesenchymal cells were used within 12 passages for subsequent experiments at 50–75% of their saturation density unless otherwise specified.

Characterization of recovered cells

The cells of both populations were characterized by morphological and immunohistochemical criteria as previously described (21). Morphologically by phase contrast, the cells demonstrated the typical spindle shaped appearance of lung fibroblasts and ultrastructurally, the characteristic features of myofibroblasts were observed. Immunohistochemical analysis indicated that the cells displayed determinants characteristic of mesenchymal cells (vimentin, α-smooth muscle actin, and desmin), but did not display determinants of endothelial cells (Factor VIII and ulex), epithelial cells (cytokeratin and epithelial membrane antigen), or leukocytes (CD45). In addition, acute lung injury mesenchymal cells displayed prominent transverse actin fibers, a feature of migrating cells, by rhodamine phalloidin staining.

Immunohistochemical staining for CD44

Immunohistochemical studies were performed on frozen sections prepared from lung specimens obtained from patients who died of acute alveolar fibrosis and from surgical specimens showing normal lung parenchyma. The avidin–biotin complex immunoperoxidase technique was used. The sections were incubated overnight (16 h) with anti–CD44 antibody (BU52; The Binding Site, Inc., San Diego, CA) at a 1:4,000 dilution. As controls, nonimmune mouse serum and an IgG isotype–matched control antibody (mouse IgG, Kappa; Sigma Chemical Co., St. Louis, MO) were used. Negative controls consisted of lung tissue from acute lung injury patients incubated with an “irrelevant” primary antibody (antisynaptophysin antibody, 1:70 dilution; Boehringer-Mannheim Biochemicals, Indianapolis, IN) and secondary antibody without primary antibody.

Reverse transcriptase–PCR

cDNA for PCR was synthesized by a random primer method as described by Bennett et al. (24). 1 μg of fibroblast total mRNA was incubated (5 min, 55°C) with 2 μl of 0.1 M Hexamer (Gibco Laboratories, Grand Island, NY). Subsequently, 4 μl of 5 × first strand buffer (Gibco Laboratories), 0.5 μl of 0.1 M DTT, 1 μl of each 10 mM dNTPs, and 1 μl of Superscript Plus (Gibco Laboratories) were added to diethyl procarbonate–treated water to a final volume of 20 μl. The mixture was incubated (1 h, 37°C) and enzyme inactivated (5 min, 95°C). PCR reactions were carried out in a total volume of 100 μl containing 20 μl of cDNA, 8 μl of each 10 mM dNTPs, 1 μl of 20 pmol/ml of each primer, 8 μl 10 × PCR buffer, and 2.5 U Taq polymerase (Fisher Scientific Co., Pittsburgh, PA). Primers were added when the reaction mixture was at 95°C. The cDNA was amplified for 22 cycles. The PCR amplification program was as follows: denatur-
at (0.5 min, 95°C), annealing (1.5 min, 62°C), extension (1 min, 73°C), followed by a final extension (10 min, 73°C). The oligonucleotides used as PCR primers were the CD44E3-FP and the CD44E16-RP primers as described by Bennett et al. (24). The CD44 variant exon primers were the pv2–pv10 primers as described by van Weering et al. (25).

**Western analysis**

Western analysis of both lung injury and normal fibroblasts were performed as previously described (3). Briefly, fibroblasts were washed, lysed on ice with lysis buffer (PBS, 1% Triton X-100, 0.5% sodium deoxycholate, 1 mM PMSF), and some aliquots of lysate supernatant were digested (37°C, 4 h) with chondroitinase ABC (0.1 U/ml; Seikagaku America, Inc., Rockville, MD) before electrophoresis. Proteins were subjected to SDS-PAGE 6–15% under nonreducing conditions and electrophoretically transferred (45 min, 24 V) to a 0.2-μm nitrocellulose membrane. Membranes were blocked in 10% dry milk in TTBS (150 mM NaCl, 100 mM Tris, 0.05% Tween 20), incubated with either mouse anti-human CD44 antibody (Hermes 1, a gift from Dr. Eugene Butcher), or rat anti-mouse CD44 antibody (IM7; PharMingen, San Diego, CA), washed and then incubated with the appropriate secondary antibody (goat anti-mouse or goat anti–rat IgG antibody) coupled to horseradish peroxidase and color developed. Controls consisted of nitrocellulose membranes incubated with normal mouse serum followed by the anti-mouse IgG secondary antibody.

**Immunoprecipitation and SDS-PAGE**

Acute lung injury fibroblasts were released with trypsin-EDTA, washed, resuspended to a final concentration of 106 cells/ml in PBS, pH 7.4, and placed on ice. The cells were surface labeled by the addition of 5 μCi [35S]methionine (0.0017% final concentration) and H2O2 (0.0017% final concentration) and mixed (3 min, 4°C). The oligonucleotides used as PCR primers were the CD44E3-FP and the CD44E16-RP primers as described by Bennett et al. (24). The CD44 variant exon primers were the pv2–pv10 primers as described by van Weering et al. (25). The cells were then rinsed three times with PBS, and a fluorescein-conjugated goat anti-mouse IgG antibody (Jackson ImmunoResearch Labs Inc., West Grove, PA) was applied (20 min, 22°C). The rinsed samples were mounted with coverslips and observed on an Axioshot photomicroscope (Carl Zeiss, Inc., Thornwood, NY). Controls consisted of substituting normal mouse serum for the primary antibody and mouse IgG, isotype-matched control monoclonal antibody and incubating cells with secondary antibody only.

**Immunoelectron microscopic localization of CD44**

For localization of CD44 at the ultrastructural level, fibroblasts were released with trypsin-EDTA, washed, and allowed to adhere (18 h, 37°C) to formvar-coated carbon stabilized grids that had been incubated with fibrocepin (10 μg/ml). The grids were rinsed with PBS and fixed with 1% paraformaldehyde and 0.05% glutaraldehyde (10 min, 22°C). The grids were then rinsed, and the fixation was quenched with 0.1 M glycine (5 min, 22°C). The grids were then blocked with 10% calf serum in PBS (5 min, 22°C), and then incubated with a mouse anti-human CD44 antibody (BU52), suspended and then incubated with the appropriate secondary antibody (goat anti-mouse or goat anti–rat IgG antibody) coupled to horseradish peroxidase and color developed. Controls consisted of nitrocellulose membranes incubated with normal mouse serum followed by the anti-mouse IgG secondary antibody.

**Invasion gels**

Gels composed of fibrin were prepared under sterile conditions as previously described by Brown et al. (17). Cultures of acute lung injury fibroblasts were harvested with trypsin-EDTA, washed, and resuspended in DMEM with 20% heat-inactivated calf serum at a final concentration of 106 cells/ml. Six microdroplets of 2 μl of the cell suspension were spotted on the bottom of a Falcon six-well plate (Becton-Dickson & Co.) and cells were allowed to adhere (4 h, 37°C) in a humidified incubator. Nonadhering cells were washed from the plate with PBS. Human thrombin (0.2 U/ml, Sigma Chemical Co.) was added to HPLC-DEAE–purified human fibrocepin (3 mg/ml, Sigma Chemical Co.) dissolved in a Heps–saline buffer (0.13 M NaCl, 0.025 M N-2-hydroxyethylpiperazine-N’-2-ethansulfonic acid, 0.005 M CaCl2, pH 7.4). This mixture was layered over the adherent cells and allowed to solidify (30 min, 37°C). Finally, 1 ml DMEM containing 2.5% heat-inactivated calf serum was added to cover the fibrin gel. The cells were incubated (37°C, 10% CO2) in a humidified incubator, and the cells were refed three times each week with fresh media.

Cell invasion was measured by quantifying the number of cells that invaded the overlying fibrin gel. By focusing on the bottom of the plate and then refocusing above this plane using an inverted phase contrast microscope (IMT-2; Olympus Corp., Lake Success, NY), cells that had invaded the gel could be identified clearly by their position above the original starting plane. Quantification of the number of invading cells was performed on days 1–7. Results are reported as mean number of cells invading the gel/microdroplet plus or minus the standard error of the mean of at least six microdroplets.

**Cell adhesion and migration assays**

Cell adhesion to protein-coated substrata was performed as previously described (2, 16) using 0.1–100 μg/ml fibrocepin, 0.005–5 μM fibrocepin, 3 mg/ml fibrin, 5 μg/ml-5 mg/ml hyaluronic acid, and 1–50 μg/ml laminin. Briefly, for the adhesion assays, acute lung injury fibroblasts, 50–75% confluent, were radiolabeled (18 h) with [3H]thymidine (2 μCi/ml), released with trypsin-EDTA (Gibco Laboratories), washed and resuspended to a final concentration of 5 × 104 cells/ml, annealing (1.5 min, 62°C), extension (1 min, 73°C), followed by a final extension (10 min, 73°C). The oligonucleotides used as PCR primers were the CD44E3-FP and the CD44E16-RP primers as described by Bennett et al. (24). The CD44 variant exon primers were the pv2–pv10 primers as described by van Weering et al. (25).
Inhibition assays: anti–CD44 monoclonal antibody

Inhibition assays using a mouse anti–human CD44 monoclonal antibody (BU52; The Binding Site, Inc.) were performed as previously described (26). Briefly, for the adhesion assay, radiolabeled cells were preconditioned with fibronec tin (1–10 mM), fibrinogen (0.5–5 mM), or hyaluronic acid (50 μg/ml–5 mg/ml). The lower wells of the modified Boyden chamber were filled with DMEM containing 5 mg/ml BSA. Acute lung injury fibroblasts, 50–75% confluent, were released with trypsin-EDTA, and resuspended in DMEM with 5 mg/ml BSA at a concentration of 10^6 cells/ml. These cells were added to the upper wells at 4.5 × 10^3 cells/well and migration to the underside of the filters was measured after 4 h at 37°C.

**Inhibition assays: anti–CD44 monoclonal antibody**

Inhibition assays using a mouse anti–human CD44 monoclonal antibody (BU52; The Binding Site, Inc.) were performed as previously described (26). Briefly, for the adhesion assay, radiolabeled cells were preconditioned with serial dilutions of the antibody (30 min, 37°C). Cells were added to the extracellular matrix protein–coated plates and incubated (1 h, 37°C). The wells were washed and adherent cells quantitated as for the cell adhesion assay, as described above.

For the migration assay, acute lung injury fibroblasts were preincubated (30 min, 37°C) with serial dilutions of the anti–CD44 antibody and added to the upper wells of the modified Boyden chambers as described above.

For the invasion assay, the cells were allowed to attach to the surface of the tissue culture plate for 4 h, and then overlayed with fibrinogen and allowed to clot by the addition of thrombin for an additional hour. Then serial dilutions of the monoclonal antibody were added to the media used to feed the cells.

Control assays were performed by substituting an isotype-matched control monoclonal antibody (mouse IgG, Kappa), normal mouse IgG and anti–α3 integrin monoclonal antibody (Chemicon International, Inc., Temecula, CA) for the anti–CD44 monoclonal antibody.

**β-D-xyloside and chondroitinase ABC pretreatment**

For adhesion, migration, and invasion assays, cells were treated with 1 mM β-D-xyloside (β-nitrophenyl-β-D-xylopyranoside; Sigma Chemical Co.) for 48 h to inhibit CSPG synthesis by replacing the medium of cell cultures with DMEM containing 2.5% heat-inactivated calf serum, with or without β-D-xyloside. β-D-xyloside was also included in the medium during the assays. For invasion assays, fibrin gels used in the β-D-xyloside experiments were composed of fibrinogen dissolved in Hepes–saline buffer containing β-D-xyloside.

For chondroitinase ABC treatment, cells were pretreated with varying concentrations (0.1–0.5 U/ml) of chondroitinase ABC (15 min, 37°C, Sigma Chemical Co.) before adhesion and migration assays as described by Faassen et al. (5). Chondroitinase ABC was also included in the cell medium during the adhesion and migration assays.

**Hyaluronidase treatment of fibrinogen, fibronec tin, and fibrin gels**

Human fibrinogen (3 mg/ml) was dissolved in Hepes–saline buffer containing 20 turbidity reducing units/ml of Streptomyces hyaluronidase (Calbiochem-Behring Corp., San Diego, CA) and incubated (3 h, 37°C). Human thrombin (0.2 U/ml) was added to the hyaluronidase-treated fibrinogen solution and this mixture was then layered over adherent fibroblasts and allowed to solidify (30 min, 37°C). 1 ml of DMEM containing 2.5% heat-inactivated calf serum was added to cover the gels, which were incubated as described above.

For adhesion and migration assays, solutions of fibrinogen and fibronec tin were pretreated with 20 turbidity reducing units/ml of Streptomyces hyaluronidase (3 h, 37°C) before coating the tissue culture plastic or polycarbonate filters, respectively.

**Statistical analysis**

All the data were expressed as mean±SEM performed in triplicate unless otherwise indicated.

**Results**

**Immunohistochemistry.** To link CD44 with the development of tissue fibrosis, one would predict that fibroblasts comprising newly formed fibrotic tissue would express CD44. Immunohistochemical analysis of lung tissue obtained from patients who died from the fibroproliferative disorder of acute alveolar fibrosis after lung injury was performed to examine the spatial distribution and anatomic location of CD44-expressing mesenchymal cells. Sheets of actively proliferating spindle (mesenchymal) cells expanding the interstitium and penetrating into alveolar spaces were strongly immunoreactive with anti–CD44 antibody (Fig. 1, A and B). Immunoreactivity was also found in intraalveolar macrophages and bronchial/bronchiolar smooth muscle, but not vascular smooth muscle. Normal control lung immunostained with anti–CD44 antibody showed positive staining for macrophages and a lack of immunoreactivity in the interstitium (Fig. 1 C). In contrast, fibrotic lung stained with an IgG isotype-matched control antibody did not show any immunoreactive cells (Fig. 1 D). Normal control lung stained with the IgG isotype-matched control antibody also did not show immunoreactive cells (data not shown). In addition, normal and acute lung injury lung tissue did not show CD44 immunoreactivity when the anti–CD44 primary antibody was omitted and an “irrelevant” antibody (antisynaptophsin) was substituted in its place (data not shown). Also, no immunoreactivity was seen when fibrotic and normal lung tissue were stained with secondary antibody without primary antibody (data not shown).

**Analysis of CD44 mRNA transcripts in acute lung injury fibroblasts.** Reverse transcription (RT)-PCR was performed to determine which mRNA transcripts corresponding to different CD44 isoforms were present in acute lung injury and normal fibroblasts. RT-PCR using primers located in the common exons E3 and E16 generated one PCR product of ~450 bp (Fig. 2, lane 1) using mRNA from either acute lung injury or normal fibroblasts (data shown for acute lung injury fibroblasts only). The ~450-bp product is the predicted size (469 bp) for the “standard” isoform of CD44 (CD44H), which corresponds to the 85-kD CD44 protein.

**Figure 1.** CD44-expressing mesenchymal cells are found throughout newly formed fibrotic lung tissue obtained from patients who died from the fibroproliferative disorder of acute alveolar fibrosis after lung injury. (A and B) Lung tissue obtained immediately after death was snap frozen and immunostained with anti–CD44 monoclonal antibody. Strong immunoreactivity was detected in actively proliferating interstitial and intraalveolar spindle (mesenchymal) cells that obliterated the normal alveolar architecture. Vascular smooth muscle cells were negative (A, long arrow); however, a positive staining pattern was observed in airway-associated smooth muscle (B, arrowhead). (C) Normal control lung immunostained with anti–CD44 antibody showed positive staining for intraalveolar macrophages. (D) Fibrotic lung stained with an IgG isotype-matched control antibody showed a lack of immunoreactivity (avidin–biotin-complex/hematoxylin stain, 50×).
RT-PCR was also used to examine for expression of CD44 transcripts containing variant exons. As expected based on the PCR results using primers located in the common exons showing only one band, no PCR products were apparent when PCR analysis was performed using the variant exon primers pv2–pv10 as forward primers and the E16 PCR primer as the reverse primer (data not shown). Negative controls consisting of PCR of primers only (no DNA) and PCR of RNA (no reverse transcriptase reaction) yielded no PCR products (Fig. 2, lanes 2 and 3). These data indicated that both normal and acute lung injury fibroblasts express mRNA for the 85-kD isoform of CD44.

**Acute lung injury fibroblast CD44 analysis.** To identify the presence and determine the molecular mass of acute lung injury and normal fibroblast CD44, Western analysis of cell lysates and immunoprecipitation of 125I surface-labeled proteins using a mouse anti–human CD44 monoclonal antibody were performed. Since CD44 may be modified by the addition of chondroitin sulfate sidechains to the extracellular domain of the core protein, aliquots of the cell lysates (Western analysis) and 125I surface-labeled proteins (immunoprecipitation) were digested by chondroitinase ABC before electrophoresis. The undigested and chondroitinase ABC–digested cell lysates and immunoprecipitated 125I-labeled proteins were analyzed by 6–15% SDS-PAGE under nonreducing conditions.

Western analysis of undigested and digested cell lysates from both acute lung injury and normal fibroblasts revealed the presence of a broad region of immunoreactivity ranging from Ͼ 85 to 97 kD (Fig. 3 A, lanes A–D). Data is shown for Hermes 3 (mouse anti–human CD44 antibody) only. Similar results were obtained using Hermes 1, IM7, and BU52 monoclonal antibodies (rat anti–human, rat anti–mouse, and mouse anti–human CD44 antibodies). This data is consistent with the PCR analysis showing the presence of the 450-bp PCR product that corresponds to the Ͼ 85–95-kD CD44 protein. No immunoreactivity was present when the blots were incubated with normal mouse serum or IgG isotype-matched control antibody in place of the anti–CD44 antibody (data not shown).

In addition, one predominant protein with a molecular mass of Ͼ 85 was immunoprecipitated from lung injury fibroblasts with the Hermes 1 and 3, and BU52 anti–CD44 monoclonal antibodies (Fig. 3 B, lanes A and B; data shown for Hermes 3 anti–CD44 antibody).

**Immunoprecipitation.** To identify the 85-kD fibroblast CD44 isoform by Western analysis and immunoprecipitation with anti–CD44 monoclonal antibodies. To identify the presence and determine the molecular mass(es) of acute lung injury and normal fibroblast CD44, Western analysis of fibroblast lysates and immunoprecipitation of 125I surface-labeled detergent-extracted proteins using a mouse anti–human CD44 monoclonal antibody (Hermes 3) was performed. Because CD44 may be modified by the addition of chondroitin sulfate, aliquots of the cell lysates or surface-labeled proteins were digested with chondroitinase ABC before electrophoresis. The cell lysates and immunoprecipitated proteins were analyzed by 6–15% SDS-PAGE under reducing conditions. (A, lanes A and B) Western analysis of undigested and chondroitinase-digested normal fibroblast lysates. (A, lanes C and D) Western analysis of undigested and chondroitinase-digested acute lung injury fibroblast lysates. (B, lanes A and B) Undigested and chondroitinase-digested Hermes 3 immunoprecipitated proteins from acute lung injury fibroblasts. (B, lanes C and D) Undigested and chondroitinase-digested proteins immunoprecipitated with monoclonal antibodies that only recognize the unsaturated bonds of either 4- or 6-sulfated chondroitin sulfate residues that remain attached to the core protein after chondroitinase digestion.
body only). This corresponds exactly to the large broad region of immunoreactivity apparent in the Western analysis. Similar to the Western analysis, there was no difference between chondroitinase-digested and -undigested samples, indicating that the 85-kD protein isolated from fibroblasts is not significantly modified by chondroitin sulfate. Several faint bands were visible in both the undigested and digested lanes of immunoprecipitated proteins at < 85, 110, and 150 kD that have not been identified further. In light of the PCR and Western analysis data, it is unlikely that these bands represent additional CD44 isoforms and may represent nonspecific binding. As a control, rabbit anti–mouse IgG antibody coupled to protein A agarose beads failed to bind the proteoglycan core proteins (data not shown).

To further examine the issue of whether the CD44 protein was modified by the addition of chondroitin sulfate sidechains, 125I surface labeled detergent extracted proteins derived from acute lung-injury fibroblasts were immunoprecipitated using two mouse monoclonal antibodies that recognize the unsaturated bonds of 4-O and 6-O sulfated chondroitin sulfate residues that remain attached to proteoglycan core proteins after chondroitinase ABC digestion. No immunoprecipitated protein was present in the chondroitinase-digested lane at 85 kD (Fig. 3 B, lane D), indicating that the 85-kD CD44 protein is not significantly modified by chondroitin sulfate. In addition, as expected, no bands were present in the undigested lane (Fig. 3 B, lane C).

**Location of acute lung injury fibroblast cell surface CD44.**

To determine the location of CD44 on the surface of migrating fibroblasts, the cells were labeled with an antibody to CD44. The fibroblasts were then examined by either indirect immunofluorescence microscopy (fluorescein-conjugated secondary antibody) or indirect whole-cell mount electron microscopy (gold-conjugated secondary antibody).

The epitope recognized by the anti–CD44 antibody (BU52) displayed an extensive, homogenous distribution over the cell surface when viewed by fluorescein microscopy. Bright blue–green labeling was seen on peripheral edges, including lamellipodia and filopodia, as well as lighter labeling of the dorsal surface. Some migrating cells were observed to possess densely labeled patches on the leading ruffled edges (Fig. 4 A). Many cells displayed fine, punctate labeling of their dorsal areas, often coalescing to brightly labeling extrusions. Control cells unlabeled with the primary antibody demonstrated a faded orange–brown appearance (data not shown). Cells incubated with normal mouse serum or IgG, isotype-matched control antibody were also essentially unlabeled (data not shown).

When examined by whole-cell mount transmission electron microscopy, this diffuse homogeneous appearance was also observed (Fig. 4 B). Of particular relevance to cell migration, filopodia and lamellipodia, which are highly motile structures found at the leading edge of migrating fibroblasts and which participate in cell locomotion, were also labeled (Fig. 4, C and D). Control experiments were performed in which the anti–CD44 antibody was replaced with either normal mouse serum or an IgG, isotype-matched control antibody. Essentially, no labeling of control specimens was observed (Fig. 4, E and F). These data indicate that the CD44 cell surface matrix receptor is present in a homogeneous pattern over the surface of the cell and can be found at the leading edge of motile cells and on filopodia and lamellipodia, structures involved in cell motility.

**Cell surface CD44 mediates acute lung injury fibroblast invasion of a fibrin matrix.** Having identified the presence and location of CD44 on migrating fibroblasts, we next sought to examine the importance of cell surface CD44 in mediating acute lung injury fibroblast invasion of fibrin by employing three-dimensional fibrin gels, using the technique described by Brown et al. (17). Acute lung injury fibroblasts plated in microliter dots beneath a layer of polymerized fibrin rapidly extended long, thin cytoplasmic processes into the fibrin gel, and then invaded the overlying gel out of the plane of focus of the bottom of the plate (Fig. 5). 1 d after plating, a few cells in each microwell had invaded the gel. By day 5, large numbers of cells had invaded the fibrin gel matrix (Fig. 6).

To evaluate a potential role of cell surface CD44 in mediating fibroblast invasion of a fibrin matrix, acute lung injury fibroblast invasion was observed in the presence of varying concentrations of anti–CD44 monoclonal antibody. Fibroblasts cultured in the presence of anti–CD44 monoclonal antibody exhibited a dose-dependent reduction in invasion of the fibrin gel (Fig. 6). At anti–CD44 antibody concentrations of 10 and 20 μg/ml, fibroblast invasion into the fibrin matrices was completely inhibited (Fig. 6). Interestingly, at low concentrations of anti–CD44 antibody (0.01 μg/ml), fibroblast invasion at days 3 and 4 of the assay was slightly elevated above controls. However, at termination of the invasion assay on day 5, no significant difference in fibroblast invasion into fibrin was apparent when cells were cultured in the presence of low concentrations of anti–CD44 antibody compared with control. No inhibition of fibroblast invasion into the fibrin gels was observed in the presence of the mouse IgG, isotype-matched control monoclonal antibody (Fig. 6), normal mouse IgG, or anti-α5 integrin antibody (data not shown). Additionally, similar to acute lung injury fibroblasts, normal lung fibroblasts were able to invade fibrin gels. Invasion of these gels was inhibited in a concentration-dependent fashion by anti–CD44 antibody (data not shown). These studies indicate that cell surface CD44 is necessary for both acute lung injury and normal fibroblast invasion of three-dimensional fibrin matrices.

The Western analysis and immunoprecipitation data indicated that the 85-kD acute lung injury CD44 protein was not significantly modified by chondroitin sulfate. We further examined whether small amounts of chondroitin sulfate on CD44 might mediate fibroblast invasion. To evaluate the potential role of chondroitin sulfate in mediating fibroblast invasion of fibrin, cell invasion was observed in the presence of 1 mM β-D xyloside. The number of cells invading the gel at day 5 in the presence or absence of β-D xyloside was not statistically significant (27 ± 4 vs 30 ± 4, respectively). This data is consistent with the interpretation that chondroitin sulfate, which may modify CD44, does not play a significant role in fibroblast invasion of fibrin.

To examine whether small amounts of hyaluronic acid possibly contaminating the fibrin gels might be playing a role in mediating fibroblast invasion, the fibrin gels were treated with hyaluronidase. Fibroblasts were capable of invading hyaluronidase-treated fibrin gels as effectively as untreated fibrin gels (data not shown).

**Anti–CD44 antibody blocks acute lung injury fibroblast migration on fibronectin, fibrinogen, and hyaluronic acid.** To further examine the role of CD44 in mediating acute lung injury fibroblast invasion of a fibrin matrix, the effects of mouse anti–human CD44 monoclonal antibodies on fibroblast motility were examined in Boyden chamber–type migration assays. Acute lung injury fibroblasts preincubated with the anti–CD44 monoclonal antibody exhibited a dose-dependent reduction in
migration on fibronectin (10 μg/ml) (Fig. 7 A). At 20 μg/ml, anti–CD44 monoclonal antibody eliminated fibroblast migration on fibronectin. No reduction in acute lung injury fibroblast migration occurred when the cells were preincubated with a normal mouse IgG control antibody, mouse IgG3 isotype-matched control monoclonal antibody, or anti-α2 integrin antibody.

The role of CD44 in mediating fibroblast migration on fibrinogen (0.5 μM) was also examined. Acute lung injury fibroblasts preincubated with anti–CD44 monoclonal antibody exhibited a dose-dependent reduction in migration on fibrinogen (Fig. 7 B). Anti–CD44 monoclonal antibody at 10 and 20 μg/ml completely inhibited fibroblast migration on fibrinogen. No reduction in fibroblast migration on fibrinogen occurred when the cells were preincubated with control antibodies. In addition, pretreatment of fibronectin or fibrinogen solutions with hyaluronidase had no effect on fibroblast migration (data not shown).

Since hyaluronic acid accumulates in the wound provisional matrix (12–15) and has been associated with cell motility (8, 19), and since CD44 has been reported as a matrix adhesion receptor for hyaluronic acid (10), fibroblast migration on hyaluronic acid was examined after preincubation with anti–CD44 antibody. Fibroblast migration on hyaluronic acid (5 mg/ml) was inhibited in a dose-dependent manner by anti–CD44 antibody (Fig. 7 C). At an antibody concentration of 20 μg/ml, fibroblast migration on hyaluronic acid was completely inhibited. Control antibodies did not inhibit fibroblast migration on hyaluronic acid.

Similar to acute lung injury fibroblasts, anti–CD44 antibody also inhibited normal lung fibroblast migration on fibronectin, fibrinogen, and hyaluronic acid in a concentration-dependent fashion (data not shown).

Using low concentrations (0.01 μg/ml) of anti-CD44 antibody in the invasion assay, fibroblast invasion of fibrin was slightly elevated on days 3 and 4 of the assay compared with control. However, upon termination of the invasion assay at day 5, there was no significant difference in fibroblast invasion of fibrin when cultured in the presence of low concentrations of anti–CD44 antibody compared with control. Similarly, there was no significant difference in fibroblast migration on fibronectin, fibrinogen, or hyaluronic acid when the cells were cultured in the presence of low concentrations (0.01 or 0.1 μg/ml) of anti–CD44 antibody compared with control antibody.

To examine the potential role of chondroitin sulfate modification of CD44 on cell motility, the effects of β-D xyloside and chondroitinase ABC on fibroblast motility were evaluated. Fibroblast motility on fibronectin coated filters were not affected by 1 mM β-D xyloside (70±6) compared to no treatment (65±5). Similarly, migration on fibronectin was not altered significantly by 0.1 or 0.5 U/ml of chondroitinase ABC (53±5 and 48±4, respectively) compared to control (46±6).

**CD44 mediates fibroblast adhesion to fibronectin, fibrinogen, fibrin, and hyaluronic acid, but not to laminin.** To determine whether cell surface CD44 plays a role in fibroblast adhesion to various wound provisional matrix molecules, thereby facilitating motility and invasion, fibroblasts were preincubated with anti–CD44 monoclonal antibody in varying concentrations.

Fibroblasts preincubated with the anti–CD44 monoclonal antibody exhibited a dose-dependent reduction in adhesion on fibrinogen, fibrin, and hyaluronic acid.
fibronectin (10 μg/ml) (Fig. 8A). At 20 μg/ml, adhesion to fibronectin was decreased by 70%. Cell appearance by phase contrast microscopy indicated that the cells remained rounded up and unable to spread in the presence of antibody (Fig. 9A). No reduction in fibroblast adhesion occurred when the cells were preincubated with control monoclonal antibodies (Fig. 8A) and the cells were capable of spreading on fibronectin in the presence of control antibodies (data shown for mouse IgG1 antibody) (Fig. 9B).

Similarly, anti–CD44 monoclonal antibody blocked fibroblast adhesion to fibronectin in a dose-dependent fashion (Fig. 8B). At the maximal concentration of antibody tested, 20 μg/ml, fibroblast adhesion to fibronectin (0.5 μM) was reduced by ~50%. Control antibodies had no effect on fibroblast adhesion to fibronectin. Consistent with the invasion and migration assay results, pretreatment of fibronectin and fibronectin solutions with hyaluronidase did not effect fibroblast adhesion (data not shown).

Fibroblast adhesion to fibrin was examined by layering fibroblasts onto a fibrin gel. Fibroblast adhesion to the fibrin surface was blocked by the anti–CD44 monoclonal antibody in a dose-dependent fashion (Fig. 8C). At 20 μg/ml antibody, fibroblast adhesion to fibrin was reduced by 47%. The appearance of fibroblasts adhering to the fibrin gel indicated that some cells could still attach to the surface of the fibrin gel, but could not spread normally in the presence of anti–CD44 antibody (Fig. 9C). Control monoclonal antibodies had no effect on fibroblast adhesion to fibrin (Fig. 8C) and the cells were capable of spreading on the surface of the fibrin gel in the presence of control antibodies (data shown for mouse IgG1 antibody) (Fig. 9D).

The 85-kDa isoform of CD44, also termed CD44H, is an adhesion receptor for hyaluronic acid (10). To determine whether acute lung injury fibroblasts use CD44 to adhere to hyaluronic acid, the cells were preincubated with the anti–CD44 monoclonal antibody. Fibroblast adhesion to hyaluronic acid (5 mg/ml) was inhibited in a dose-dependent manner by anti–CD44 antibody (Fig. 8D). Anti–CD44 monoclonal antibody, at a concentration of 20 μg/ml, inhibited fibroblast adhesion to hyaluronic acid by 70%. Control antibodies did not inhibit fibroblast attachment to hyaluronic acid.

In contrast, anti–CD44 monoclonal antibody did not block fibroblast adhesion to laminin (Fig. 8E). At 20 μg/ml antibody, no reduction in cell adhesion occurred. Importantly, by phase contrast microscopy, the cells were capable of attaching and spreading on laminin in the presence of anti–CD44 antibody (Fig. 9E). Cells treated with control antibodies attached and spread normally (Figs. 8E and 9F). This indicates that the effect of anti–CD44 monoclonal antibody in blocking fibroblast adhesion to fibronectin, fibrinogen, and fibrin was not due to a toxic effect on the cells. Similar results for the adhesion assay were obtained using normal lung fibroblasts. These data are consistent with the interpretation that CD44 is a fibroblast adhesion receptor for the provisional matrix proteins fibronectin, fibrinogen, fibrin, and hyaluronic acid, but not laminin, a component of the basement membrane.

Similar to the invasion and migration assay results, treatment of fibroblasts with β-D xyloside and chondroitinase ABC did not affect fibroblast adhesion. Fibroblast adhesion to fibronectin in the presence or absence of 1 mM β-D xyloside was 64±9 and 65±13, respectively. Additionally, fibroblast adherence to fibronectin was not significantly decreased in the presence of 0.1 or 0.5 U/ml chondroitinase ABC (62±11 and 58±8,
Fibroblast Invasion of a Fibrin Matrix Is Mediated by CD44

respectively). Collectively, the Western and immunoprecipitation data together with the functional assay results indicate that chondroitin sulfate, which may modify CD44, does not have a substantial role in fibroblast adhesion, migration, or invasion.

Discussion

Fibrosis results when myofibroblasts invade the wound fibrin provisional matrix. Matrix receptors on the cell surface mediate cell adhesion, migration, and invasion of the extracellular matrix. The present study provides evidence that CD44, a matrix receptor on the surface of the fibroblast, plays a role in mediating the fibrotic response after lung injury. Importantly, using immunohistochemical techniques, CD44-expressing mesenchymal cells were seen throughout newly formed fibrotic tissue in the injured lung. We have determined that acute lung injury fibroblasts express the 85-kD isoform of CD44 on their cell surface. Using indirect immunofluorescence microscopy, CD44 was found to be distributed over the cell surface and could be detected concentrated along the leading edge of some motile fibroblasts. Whole-cell mount transmission electron microscopy also detected CD44 uniformly labeling the cell surface and importantly, was found labeling filopodia and lamellipodia, that are highly motile structures at the leading edge of migrating cells that participate in cell motility. The importance of CD44 in mediating fibroblast migration and invasion into fibrin was demonstrated by inhibiting the function of CD44 with monoclonal antibodies. Fibroblast migration on provisional matrix proteins and invasion of a fi-

Figure 8. Fibroblast adhesion to the wound provisional matrix proteins fibronectin, fibrinogen, fibrin, and hyaluronic acid are blocked by anti-CD44 antibody. Acute lung injury fibroblasts radiolabeled overnight with [3H]thymidine were released from the flasks and preincubated for 30 min with varying concentrations of anti-CD44 antibody (○) or isotype-matched control antibody (△) and examined for their ability to adhere on either the provisional matrix proteins fibronectin (A), fibrinogen (B), fibrin (C), hyaluronic acid (D), or laminin (E). Data is expressed as percentage adhesion = (DPM attached/DPM added) × 100.
brin matrix was completely inhibited by treatment with anti-
CD44 monoclonal antibodies. We have determined that dis-
ruption of fibroblast cell surface CD44 function by anti–CD44
antibody inhibits adhesion to various components of the
wound provisional matrix including fibrin, fibrinogen, and fi-
bronectin, but not for laminin, a component of basement
membranes. Collectively, these data are consistent with the hy-
pothesis that CD44 functions as a matrix adhesion receptor on
the surface of fibroblasts, thereby mediating motility and inva-
sion of the wound provisional matrix resulting in the formation
of fibrotic tissue.

Multiple isoforms of CD44 exist as a result of alternative
splicing of a series of exons. The diversity of CD44 can be fur-
ther amplified by the differential use of glycosaminoglycan at-
tachment sites on its extracellular domain. For example, vari-
ous isoforms of CD44 may be modified by the addition of

**Figure 9.** Phase contrast microscopic appearance of adhesion assay. Shown are the phase contrast appearance of fibroblasts cultured in the pres-
ence of either anti–CD44 antibody (A, C, E) or IgG1 isotype-matched control antibody (B, D, F) and adhering to fibronectin (A and B), fibrin (C and D), or laminin (E and F) (200×). Note round appearance of cells adhering to fibronectin and fibrin in the presence of anti–CD44 antibody. Also note spread appearance of fibroblasts adhering to laminin in the presence of anti–CD44 antibody.
chondroitin sulfate. The chondroitin sulfate on CD44 appears to play important roles in mediating the migration of several cell types (5, 27). Our data indicate that fibroblasts express one CD44 isoform, the 85-kD, or standard isoform, which by Western and immunoprecipitation analysis does not appear to be modified by chondroitin sulfate.

Importantly, various isoforms of CD44 have been associated with enhanced migration and invasion of transformed cells. For example, the 85-kD isoform of CD44, also termed CD44H, promotes melanoma cell migration on hyaluronate-coated surfaces (8, 28). In addition, a 110-kD isoform of CD44, modified by the addition of chondroitin sulfate in mouse melanoma cells, mediates their invasion of collagen matrices (5). Furthermore, transfection of the cDNA of a large molecular weight (150–200 kD) variant isoform of CD44, characterized by the presence of variant exon 6, conferred metastatic behavior to a nonmetastatic rat pancreatic tumor line (6, 7). In the present study, the 85-kD isoform of CD44 is the predominant isoform on the surface of acute lung injury and normal fibroblasts. The 85-kD isoform of CD44 has been reported to be a matrix adhesion receptor for hyaluronic acid. Our adhesion and migration assay data are consistent with this finding and indicate that the 85-kD isoform of CD44 found on acute lung injury fibroblasts also mediates their adhesion and migration on hyaluronic acid.

CD44 has also been shown to be a matrix receptor for fibronectin and type I collagen (29, 30). Our adhesion assay data suggest that fibroblast CD44 functions as an adhesion receptor for a variety of wound provisional matrix proteins including fibrin/fibronogen, in addition to fibronectin, and hyaluronic acid. However, whether fibroblast CD44 mediates adhesion or migration to fibrinogen by directly interacting with fibrinogen or by an indirect mechanism remains uncertain. Regarding an indirect mechanism, it has been proposed that hyaluronic acid bound to fibrin may provide the stimulus for cell migration during the wound healing process (31). In this model, a concentration gradient of hyaluronic acid bound to fibrin in solid phase supports the directed migration of fibroblasts (haptotaxis). To begin to address the issue of whether CD44 directly or indirectly interacts with fibrinogen, we have performed adhesion, migration, and invasion assays using HPLC-DEAE purified fibrinogen and fibrinogen pretreated with hyaluronidase. Fibroblasts were capable of attaching and migrating on fibrinogen-coated surfaces and invading fibrin matrices using both HPLC-purified and hyaluronidase-treated fibrinogen. These data suggest that fibroblast CD44 may be able to directly interact with fibrin, thereby mediating cell adhesion and migration. However, reagents other than fibrinogen used in these assays may be contaminated with hyaluronic acid. Therefore, the issue of whether CD44 interacts directly or indirectly with fibrinogen remains to be defined. Interestingly, CD44 does not appear to promote fibroblast attachment to laminin, a component of the basement membrane. Furthermore, our ultrastructural analysis data is consistent with a role for CD44 as a surface matrix adhesion receptor involved with cell locomotion. CD44 was found to be distributed uniformly over the surface of the cell. Important however, was the finding that CD44 could be found concentrated along the leading ruffled edge of some migrating fibroblasts and was present on filopodia and lamellipodia, which are highly motile structures on the leading edge of migrating cells that are involved in cell movement. Therefore, since fibroblast CD44 can be found on cellular structures that participate in cell migration, this suggests a role for this adhesion receptor in fibroblast migration.

Previous work has implicated fibroblast cell surface CD44 with the development of fibrosis, but direct evidence identifying CD44 with fibroblast motility and invasion of the wound fibrin provisional matrix has been lacking. In the first study to link fibroblast CD44 with the fibrotic response, Messadi and Bertolami (20) found increased expression of CD44 in hypertrophic scar fibroblasts compared to normal skin fibroblasts. The current study provides direct evidence that fibroblast cell surface CD44 mediates fibroblast migration and invasion of a fibrin matrix. Employing the fibrin gel invasion assay, blockage of CD44 function with monoclonal antibodies eliminated the ability of fibroblasts to invade the fibrin matrix. Furthermore, prior studies have determined that after the onset of tissue injury, a meshwork of fibrin, rich in fibronectin and hyaluronan, accumulates in the wound extracellular space (1, 12–15). Over several days, this provisional matrix becomes organized by invading fibroblasts. This temporal sequence of fibronectin and hyaluronic acid accumulation in the provisional matrix followed by fibroblast invasion is important in light of the results of our adhesion and migration assays. Blockage of CD44 function with monoclonal antibodies effectively inhibited fibroblast adhesion and migration on the provisional matrix proteins, hyaluronan, and fibronectin. These results suggest that CD44 interaction with fibronectin and hyaluronan are important in fibroblast motility. Importantly, our immunohistochemical analysis further links fibroblast cell surface CD44 with the development of fibrosis. We have identified CD44-expressing fibroblasts in newly formed fibrotic tissue in the acutely injured lung. Taken together, these data provide strong support for the role of CD44 in mediating fibroblast migration and invasion of the fibrin provisional matrix and the subsequent development of tissue fibrosis.

Our data indicate that both acute lung injury and normal fibroblasts express the 85-kD isoform of CD44. In addition, both lung injury and normal fibroblast invasion of fibrin matrices can be blocked by anti–CD44 antibody, indicating a role for CD44 in fibroblast invasion of the provisional matrix after organ/tissue injury. Since both normal and lung-injured fibroblasts use CD44 for adhesion and migration, as well as invasion of fibrin, this suggests that CD44 use may not be restricted to the fibrotic disease state, but may also be involved in normal fibroblast function. However, since “normal” lung fibroblasts in culture have been extensively manipulated, one cannot be certain that their phenotype is indeed characteristic of normal fibroblasts in vivo. Consistent with this concept, depending on culture conditions, normal fibroblasts in culture may display several morphologic and biochemical markers characteristic of wound fibroblasts such as stress fibers, gap junctions, high amounts of actin, and α-smooth muscle actin (32).

Our immunohistochemical analysis performed on lung-injured tissue demonstrates sheets of CD44-positive mesenchymal cells comprising newly formed fibrotic lesions. This result can be interpreted several different ways. First, there exists the possibility that expansion of a small subpopulation of CD44-positive fibroblasts may play a crucial role in fibrogenesis. Alternatively, in the injured alveolar microenvironment, a change in the fibroblast phenotype from a quiescent, CD44-negative cell (or low level of expression) to an activated state may result in a population of CD44-positive cells. The data by Messadi and Bertolami (20), which demonstrate that
CD44 expression is increased in hypertrophic scar fibroblasts compared with normal skin fibroblasts supports the latter hypothesis. Recent work indicates that lung fibroblasts undergo phenotypic modulation into myofibroblasts during bleomycin-induced pulmonary fibrosis (33). Moreover, the presence of transforming growth factor β and tumor necrosis factor α in the fibrotic lung microenvironment has been implicated in regulating the modulation of the fibroblast phenotype into a wound phenotype (34). These data, combined with our immunohistochemical analysis showing low to undetectable CD44 staining of fibroblasts in normal tissue suggest that modulation of fibroblast phenotype into CD44-expressing cells is associated with the development of fibrotic tissue. Clearly, further studies are needed to clarify the function and role of fibroblast CD44 in normal and disease states. However, our data does directly link CD44 with fibroblast migration and invasion in one particular disease state, acute lung injury.

Identifying receptors such as CD44 involved in mediating such cellular functions as fibroblast adhesion, migration, and invasion may be critical in ultimately understanding and controlling the fibrotic response. Recent studies have shown that synthetic fibronectin peptides are capable of inhibiting leukocyte adhesion to synovial tissue and suppress inflammation in a rat arthritis model (35). The key feature of this study was the finding that these peptides could interrupt leukocyte adhesion and recruitment in active, ongoing inflammatory disease. Analogously, this suggests that blocking adhesion receptor function on fibroblasts (e.g., the CD44 receptor) may provide a means of regulating the development of fibrosis in critical regions of injured organs such as the airspace after lung injury. The plausibility of this hypothesis is suggested by our invasion assays in which fibroblast invasion of the fibrin matrix could be inhibited by anti–CD44 antibody. Further investigations using animal models of fibrosis will be important in determining whether interruption of CD44 function may attenuate or arrest the fibrotic response.
