Heme oxygenase–1 (HO-1, encoded by HMOX1) dampens inflammatory reactions via the catabolism of heme into CO, Fe, and biliverdin. We report that expression of HO-1 dictates the pathologic outcome of experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis (MS). Induction of EAE in Hmox1−/− C57BL/6 mice led to enhanced CNS demyelination, paralysis, and mortality, as compared with Hmox1+/+ mice. Induction of HO-1 by cobalt protoporphyrin IX (CoPPIX) administration after EAE onset reversed paralysis in C57BL/6 and SJL/J mice and disease relapse in SJL/J mice. These effects were not observed using zinc protoporphyrin IX, which does not induce HO-1. CoPPIX protection was abrogated in Hmox1−/− C57BL/6 mice, indicating that CoPPIX acts via HO-1 to suppress EAE progression. The protective effect of HO-1 was associated with inhibition of MHC class II expression by APCs and inhibition of Th and CD8 T cell accumulation, proliferation, and effector function within the CNS. Exogenous CO mimicked these effects, suggesting that CO contributes to the protective action of HO-1. In conclusion, HO-1 or exposure to its end product CO counters autoimmune neuroinflammation and thus might be used therapeutically to treat MS.

Introduction

MS is a presumed autoimmune disorder that targets the CNS (1). Neuroinflammatory lesions associated with MS progression are triggered upon interaction of activated pathogenic Th cells with APCs within the CNS. This leads to the generation of a proinflammatory response that causes irreversible oligodendrocyte injury, neuron demyelination, and eventually axonal loss, the main pathologic hallmarks of MS (2–4).

The clinical course of MS is, in most cases, associated with transitory episodes of remission (2), suggesting that regulatory mechanisms must operate to counter neuroinflammation and/or to promote neuron regeneration. Such mechanisms may involve, but are most probably not limited to, the participation of regulatory T cells (5, 6). We hypothesized that expression of “protective genes” (5, 7) might also promote MS remission. One candidate is heme oxygenase–1 (HMOX1/HO-1), a prototypical cytoprotective and antiinflammatory stress-responsive gene (reviewed in refs. 5, 8) expressed in the CNS during the course of MS (9) and EAE (10), a well-established model of MS (11).

Under inflammatory conditions, HO-1 becomes the rate-limiting enzyme in the catabolism of heme, yielding equimolar amounts of CO, free Fe, and biliverdin (12), which is subsequently reduced into bilirubin by biliverdin reductase (reviewed in ref. 13). Induction of HO-1 by metal protoporphyrins has been shown to have salutary effects in a variety of experimental inflammatory conditions (reviewed in refs. 8, 14). The observation that in most cases, exposure to CO can mimic the protective effects of HO-1 (reviewed in refs. 8, 15) would suggest that HO-1 acts in a protective manner via the generation of CO. It is likely, however, that other end products of HO-1 activity such as biliverdin (16) and/or free Fe (by upregulating heavy chain ferritin expression, ref. 17; or cellular Fe efflux pumps, ref. 18) may exert similar effects.

Whether HO-1 modulates the pathogenesis of autoimmune neuroinflammation remained to be established, because both protective (19) and deleterious (20) effects of chemical HO-1 modulators have been demonstrated in EAE. Using HO-1–deficient (Hmox1−/−) mice, we demonstrate that expression of HO-1 inhibited inflammation, demyelination, and paralysis, preventing mortality associated with the development of EAE. We also provide evidence that induction of HO-1 using protoporphyrins modulated ongoing autoimmune neuroinflammation, thereby reverting paralysis and leading to disease remission in mice with previously established EAE. Exogenous CO mimicked this effect, which suggests that this end product of heme degradation contributes to the protective action of HO-1. Suppression of EAE was associated with inhibition of (a) leukocyte accumulation in the CNS, (b) MHC class II expression by CNS APCs, and (c) pathogenic Th cell proliferation and effector function.

Results

Expression of HO-1 counters the pathogenesis of EAE. Given that HO-1 expression in the CNS is associated with the development of both EAE and MS (10, 19, 20), and based on the well-established protective effect of HO-1 (reviewed in refs. 5, 8), we hypothesized that HO-1 might modulate the pathogenesis of EAE. When immunized with the myelin oligodendrocyte glycoprotein peptide 35–55 (MOG35-55), Hmox1−/− C57BL/6 mice developed a more severe form of EAE than did wild-type (Hmox1+/+) C57BL/6 mice (Figure 1A and Table 1), with 75% mortality in Hmox1−/− mice compared with 19% mortality in Hmox1+/+ controls (P = 0.0024; Table 1).

We tested whether induction of HO-1 by metal protoporphyrins would arrest EAE progression in Hmox1−/+ C57BL/6 mice.

Nonstandard abbreviations used: CITTA, MHC class II transcription activator; CoPPIX, cobalt protoporphyrin IX; HO-1, heme oxygenase–1; Mφ, macrophages; MOG35–55, myelin oligodendrocyte glycoprotein peptide 35–55; PLP, proteolipid protein peptide 139–151; ZnPPIX, zinc protoporphyrin IX.

Conflict of interest: The authors have declared that no conflict of interest exists.

Induction of HO-1 expression and function by administration of cobalt protoporphyrin IX (CoPPIX) after EAE onset (i.e., disease incidence, 37%; mean clinical score, 0.7 ± 0.1) reversed paralysis and led to complete disease remission in 66.6% of mice compared with controls treated with vehicle (PBS) or zinc protoporphyrin IX (ZnPPIX; Figure 1B and Table 2). To address whether similar effects would occur in other mouse strains, EAE was induced in SJL/J mice by immunization with the proteolipid protein peptide again that endogenous HO-1 activity counters neuroinflammation associated with EAE (reviewed in refs. 2–4). These were composed primarily of CD4+ Th cells, CD8+ T cells, and significant numbers of leukocytes (CD45^hi) were detected in the CNS parenchyma and meninges, respectively, compared with vehicle-treated controls (Figure 2, A–C), an effect consistent with reduction of paralysis (Figure 1, A–C). Taken together, these observations suggest that the ability of HO-1 to revert paralysis during the progression of EAE is associated with inhibition of CNS demyelination.

**HO-1 modulates the effector function of pathogenic Th cells.** Inhibition of EAE progression and relapse in SJL mice treated with CoPPIX was associated with a 87.2% ± 20% (P = 0.0033) reduction in the total number of leukocytes detected within the CNS parenchyma and meninges compared with vehicle-treated controls (Figure 2, D–G). ZnPPIX, a protoporphyrin that inhibits HO enzymatic activity, increased by 2.3-fold the total number of leukocytes (i.e., parenchyma and meninges) compared with vehicle-treated controls (P = 0.0003), suggesting that HO-1 activity counters neuroinflammation associated with EAE progression (Figure 2, D–G). However, this effect was not reflected by an increase in the clinical scores of the disease (Figure 1C).

The ability of HO-1 induction to reduce the formation of inflammatory foci in the CNS (Figure 2G) was paralleled by a similar reduction in the total number of leukocytes detected within the CNS. Significant numbers of leukocytes (CD45^hi) were detected in the CNS of C57BL/6 mice with EAE (Supplemental Figure 1, A–F; supplemental material available online with this article; doi:10.1172/JCI28844DS1). Induction of HO-1 after EAE onset in SJL/J mice prevented CNS demyelination compared with ZnPPIX- or PBS-treated controls (Figure 2, A–C), an effect consistent with reduction of paralysis (Figure 1, A–C). Taken together, these observations suggest that the ability of HO-1 to reverse paralysis during the progression of EAE is associated with inhibition of CNS demyelination.

*P = 0.0117 versus PBS-treated C57BL/6. **P < 0.05 versus PBS- and ZnPPIX-treated C57BL/6. \( \Delta \)P = 0.0278 versus PBS-treated SJL/J. \( \Delta \)P < 0.05 versus PBS- and ZnPPIX-treated SJL/J. \( \Delta \)P = 0.009 versus air-treated C57BL/6.

and CD45<sup>hi</sup>CD11b<sup>+</sup> macrophages (M<sup>φ</sup>, Figure 3A and Supplemental Figure 2). Induction of HO-1 by CoPPIX decreased by 80% ± 6% the total number of leukocytes within the CNS compared with PBS-treated controls (P < 0.001; Figure 3A). This decrease was reflected by an 83% ± 7% decrease in Th cells (P < 0.001) and a 67% ± 17% decrease in CD8<sup>+</sup> T cells (P < 0.001) compared with PBS-treated controls (Figure 3A). These data demonstrate that HO-1 induction after EAE onset significantly decreases the number of CNS leukocytes and the formation of inflammatory foci within the CNS.

We tested whether HO-1 interfered with the activation, proliferation, and/or acquisition of effector function by CNS-infiltrating Th cells. Induction of HO-1 by CoPPIX reduced by 57% ± 2% the frequency of Th cells undergoing cell cycle progression (BrDU<sup><sup>+</sup></sup>; P = 0.028) and by 51.5% ± 34% that of Th cells expressing IL-10 (Figure 3B and Supplemental Figure 3A). This suggests that induction of HO-1 suppresses Th cell proliferation within the CNS, an effect that should contribute to suppressing EAE progression.

The pathogenic function of CNS-infiltrating Th cells was also modulated by upregulation of HO-1 in that HO-1 targeted specifically the expression of IFN-γ in Th cells. Control-treated mice with EAE had 24% ± 4% CNS-infiltrating Th cells expressing IL-10 (Figure 3B) was not modulated by HO-1, an effect that should contribute to suppressing EAE progression as well.

We asked whether the protective effect of HO-1 was associated with modulation of regulatory T cells within the CNS. The frequency of forkhead box p3–positive (Foxp3<sup>+</sup>) regulatory T cells within the CNS was not modulated by HO-1 induction (Figure 3B and Supplemental Figure 3C), suggesting that the protective effect of HO-1 may act independently of regulatory T cells.

We tested whether expression of Th cell activation surface markers, including CD69, CD25, CD44, and CD62 ligand (CD62L), were modulated by HO-1 induction. We found that this was not the case for the frequency of Th cells expressing these markers (Supplemental Figure 4) or for their relative level of expression (data not shown).

The frequency of CNS-infiltrating CD8<sup>+</sup> T cells undergoing cell cycle progression (BrDU<sup><sup>+</sup></sup>) was reduced by 55% ± 21% when HO-1 was induced compared with vehicle-treated controls (P = 0.028; Figure 3C and Supplemental Figure 3D), an effect that should contribute to suppressing EAE progression (2–4). Induction of HO-1 did not modulate IFN-γ or TNF-α expression by CNS-infiltrating CD8<sup>+</sup> T cells (Figure 3C).
HO-1 and CO suppress myelin-reactive Th cell reactivation. We hypothesized that HO-1 induction might interfere with the reactivation of primed myelin-reactive Th cells that occurs in the CNS during the development of EAE and presumably also occurs in MS patients. Induction of HO-1 by CoPPiX reduced myelin-reactive Th cell proliferation by 60.5% ± 3% compared with vehicle- or ZnPPiX-treated controls (P < 0.001; Figure 4A). Moreover, HO-1 induction did not affect the proliferative response of draining lymph node Th cells to concanavalin A (ConA; Supplemental Figure 5A) or did it reduce Th cell numbers in draining lymph nodes (data not shown).

In the same experimental system, induction of HO-1 suppressed secretion of TNF-α by 64% ± 2% (P < 0.001), IFN-γ by 75% ± 2% (P < 0.001), and IL-12/23(p40) by 61% ± 16% (P < 0.01) compared with controls (Figure 4B). This suggests that HO-1 suppresses the differentiation of primed myelin-reactive Th cells toward a pathogenic effector phenotype characterized by the secretion of proinflammatory cytokines.

To assess whether suppression of Th cell reactivation in vitro was due to defective priming of naive myelin-reactive Th cells in vivo, draining lymph node Th cells (>98% CD4+) were isolated 7 days after immunization and rechallenged in vitro with MOG35–55 in the presence of naive APCs (<2% CD4+). Proliferation of myelin-reactive Th cells from CoPPiX-treated mice was similar to that of control mice (Supplemental Figure 5A), suggesting that HO-1 induction did not interfere with priming of naive myelin-reactive Th cells in vivo.

Exposure of C57BL/6 mice to CO inhibited by 71% ± 5% the proliferative response of myelin-reactive Th cells compared with control mice exposed to air under similar flow conditions (P < 0.0016; Figure 4C). In the same experimental setting, CO inhibited TNF-α secretion by 40% ± 2% (P = 0.0029) but failed to inhibit IFN-γ secretion (Figure 4D). This suggests that the immunomodulatory effect of CO may be more restricted than that of HO-1 induction.

**HO-1 expression in APCs inhibits myelin-reactive Th cell proliferation.** We reasoned that inhibition of Th cell proliferation could result from induction of HO-1 expression in Th cells (22, 23) and/or in APCs (24). To test the first possibility, Th cells were purified from MOG35–55-immunized mice in which HO-1 was induced. Proliferation of Th cells from CoPPiX-treated mice was not significantly inhibited in the presence of APCs isolated from immunized but otherwise untreated mice compared with PBS- or ZnPPiX-treated controls (Figure 4E). This suggests that HO-1 induction in Th cells is not sufficient per se to suppress Th cell proliferation.

That the antiproliferative effect of HO-1 is exerted via APCs is suggested by the following set of observations. Proliferation of purified myelin-reactive Th cells from immunized but otherwise untreated mice was inhibited by 65% ± 7% in the presence of purified APCs from immunized mice treated with CoPPiX compared with control APCs isolated from PBS- or ZnPPiX-treated immunized controls (P < 0.001; Figure 4F). Th cell proliferation was inhibited by 59% ± 3% (P < 0.01) by DCs (>98% CD11c+; Figure 4G) but not by B cells (>98% CD19+; Figure 4H) isolated from CoPPiX-treated immunized mice compared with DCs or B cells isolated from control PBS- or ZnPPiX-treated immunized mice, respectively.

Administration of CoPPiX to C57BL/6 mice after EAE onset induced high levels of HO-1 expression in CNS-infiltrating DCs (CD11c+) compared with PBS- or ZnPPiX-treated controls (Figure 5A). Similar effects were observed in vitro: CoPPiX induced a 64-fold increase in Hmox1 mRNA expression in bone marrow–derived DCs (approximately 80% CD11c+) compared with vehicle-treated controls (Figure 5B). While Hmox1 mRNA expression was also induced by ZnPPiX, this effect was significantly less pronounced than that of CoPPiX (Figure 5B). These observations are consistent with the notion that ZnPPiX can induce HO-1 expression moderately while inhibiting its activity strongly, thus acting as a potent HO-1 inhibitor (25). In the same experimental setting, CoPPiX induced HO-1 protein expression while ZnPPiX failed to do so (Figure 5B). To ensure that CoPPiX induced HO-1 expression specifically in DCs and not in a putative contaminating cell population, bone marrow–derived DCs were further purified...
The antiproliferative effect of HO-1 is exerted via APCs. Results shown are mean ± SD from triplicate samples in 1 of at least 3 independent assays, except for IL-12/23(p40) (1 assay). (A) C57BL/6 mice were treated as described in Methods. Eight days after immunization, proliferation of myelin-reactive Th cells was assessed in vitro 72 hours after addition of MOG35–55 (10 μg/ml). (B) Cytokines were assayed in the cell culture supernatants (100 μg/ml MOG35–55 for 72 hours). (C) C57BL/6 mice were exposed to air (n = 3) or CO (450 ppm; n = 3) starting 2 days prior to immunization. Th cell proliferation was assayed as in A. (D) Mice were treated as in C, and cytokines were assayed as in B. (E–H) C57BL/6 mice were treated as in A. (E) Th cells (>98% CD4+) from PBS-, CoPPIX-, or ZnPPIX-treated mice (n = 5) were cocultured with APCs (<98% CD4+) from untreated but otherwise untreated mice. Th cell proliferation was measured as in A. Th cells from untreated immunized mice were cocultured with (F) APCs (<2% CD4+). (G) DCs (>98% CD11c+), or (H) B cells (>98% B220+) from PBS-, CoPPIX-, or ZnPPIX-treated immunized mice (n = 5). Th cell proliferation was measured as in A. **P < 0.01; ***P < 0.001.

To test whether HO-1 and/or CO would affect other APC populations involved in the pathogenesis of EAE (26, 27), MHC class II expression was analyzed in microglia (CD45<sub>int</sub>CD11b<sup>+</sup>) and CNS-infiltrating Mφ (CD45<sub>high</sub>CD11b<sup>+</sup>) of C57BL/6 mice with established EAE. Induction of HO-1 starting 2 days after disease onset (approximately 40% EAE incidence) reduced MHC class II expression by 44% ± 13% in microglia (P < 0.05; Figure 6C) and by 47% ± 24% in CNS-infiltrating Mφ (P < 0.05; Figure 6D) compared with controls.

MHC class II–expressing cells in the CNS of mice with established EAE was confined to the perivascular area and associated primarily with CNS-infiltrating leukocytes, i.e., Mφ (Figure 6, E and F). Low-level MHC class II expression was also detected in the parenchyma, presumably associated with microglia (data not shown). Induction of HO-1 by CoPPIX reduced MHC class II expression in both perivascular leukocytes and microglia (Figure 6, E and F), confirming similar observations made by flow cytometry.

To address further the mechanism by which HO-1 suppressed MHC class II expression in CNS APCs, we tested whether induction of HO-1 in microglial BV2 cells would inhibit MHC class II expression. When stimulated in vitro with IFN-γ, microglial BV2 cells upregulated the expression of MHC class II (Figure 7, A and B). Induction of HO-1 by CoPPIX inhibited by 27% ± 7% MHC class II expression compared with controls (P < 0.05; Figure 7A). Exposure to CO mimicked this effect, inhibiting by 20% ± 7% MHC class II expression compared with air-treated controls (P < 0.05; Figure 7B). Induction of HO-1 or exposure to CO had no effect on CD40, CD80, or CD86 expression in BV2 cells (data not shown). Induction of HO-1 inhibited IFN-γ–driven phosphorylation of STAT-1 without affecting STAT-1 expression (Figure 7C). Induction of MHC class II transcription activator (CIITA) mRNA expression by IFN-γ was inhibited by 30% ± 11% compared with controls (P < 0.05; Figure 7D). Given the central role of STAT-1 phosphorylation and CIITA
provide evidence that endogenous HO-1 suppressed both the pathologic outcome of EAE, a well-established model of MS. We hypothesized that the protective gene HO-1 may control the neuroinflammatory diseases (5, 7). We refer to those genes as protective (7) and in inflammation and thus counter the pathogenesis of inflammation, e.g., biliverdin, may act in a similar manner (30). However, biliverdin does not suppress myelin-reactive Th cell proliferation, nor does it suppress EAE progression (Supplemental Figure 7).

Our data suggest that the mechanism underlying the protective effect of HO-1 is associated with a profound inhibition of leukocyte accumulation (Figure 2G and Figure 3A) and reactivation (Figure 3, B and C) within the CNS. This is suggested by the observation that HO-1 induction by CoPPIX administration after EAE onset reduced the number of inflammatory foci (Figure 2G) as well as the total number of CNS Th cells, CD8+ T cells, and Mφ (Figure 3A) and in addition suppressed the proliferation of the remaining Th and CD8+ T cells (Figure 3, B and C) infiltrating the CNS.

The antiproliferative effect of HO-1 was shown in vitro to be strictly dependent on DCs (Figure 4G) that express high levels of HO-1 (Figure 5, B and C). That a similar effect may occur in vivo to arrest EAE progression is suggested by the observation that DCs expressing high levels of HO-1 were detected in the CNS of CoPPIX-treated mice in which EAE progression was arrested (Figure 5A).

Induction of HO-1 leads to specific inhibition of MHC class II expression in APCs (28) (reviewed in ref. 29), the inhibitory effect of HO-1 over MHC class II expression in these cells might be explained by its ability to suppress STAT-1 phosphorylation and CIITA expression.

Discussion

There are several genes that can limit the deleterious effects of inflammation and thus counter the pathogenesis of inflammatory diseases (5, 7). We refer to those genes as protective (7) and hypothesized that the protective gene HO-1 may control the pathologic outcome of EAE, a well-established model of MS. We provide evidence that endogenous HO-1 suppressed both the severity and the mortality associated with the development of this neuroinflammatory disease (Figure 1A and Table 1). Uprogulation of HO-1 by CoPPIX acted therapeutically to reverse paralysis (Figure 1, B and C, and Table 2). That the therapeutic effect of CoPPIX is exerted via HO-1 is demonstrated by the observation that (a) CoPPIX induces the expression of HO-1 in the CNS of mice with EAE (Figure 1D) and (b) the protective effect of CoPPIX is abrogated in Hmox1−/− mice (Figure 1E).

CO contributes to the protective effects of HO-1, as exposure of Hmox1−/− mice to CO mimicked the protective effects of HO-1 (Figure 1F, Figure 4, C and D, Figure 6B, and Figure 7B). One would expect, however, that other end products of heme degradation, e.g., biliverdin, may act in a similar manner (30). However, biliverdin does not suppress myelin-reactive Th cell proliferation, nor does it suppress EAE progression (Supplemental Figure 7).

One possible explanation may be that the protective effect of HO-1 is exerted within the CNS, which biliverdin cannot enter because of its exclusion by the blood-brain barrier.

Our data suggest that the mechanism underlying the protective effect of HO-1 is associated with a profound inhibition of leukocyte accumulation (Figure 2G and Figure 3A) and reactivation (Figure 3, B and C) within the CNS. This is suggested by the observation that HO-1 induction by CoPPIX administration after EAE onset reduced the number of inflammatory foci (Figure 2G) as well as the total number of CNS Th cells, CD8+ T cells, and Mφ (Figure 3A) and in addition suppressed the proliferation of the remaining Th and CD8+ T cells (Figure 3, B and C) infiltrating the CNS.

The antiproliferative effect of HO-1 was shown in vitro to be strictly dependent on DCs (Figure 4G) that express high levels of HO-1 (Figure 5, B and C). That a similar effect may occur in vivo to arrest EAE progression is suggested by the observation that DCs expressing high levels of HO-1 were detected in the CNS of CoPPIX-treated mice in which EAE progression was arrested (Figure 5A).

Induction of HO-1 leads to specific inhibition of MHC class II expression in APCs, including DCs (Figure 6, A and B), microglia (Figure 6C), and CNS-infiltrating Mφ (Figure 6D). Induction of HO-1 expression in microglia suppresses STAT-1 phosphorylation as well as CIITA expression, 2 critical events for MHC class II expression (24) (reviewed in ref. 29) as well as in the reactivation of myelin-reactive Th cells in the CNS (31). This effect is likely to contribute to the overall protective effect of HO-1 induction, as MHC class II expression in microglia is thought to be involved in EAE pathogenesis and progression (reviewed in refs. 32, 33).

That inhibition of MHC class II accounts for the protective effect of HO-1 is supported by the association between certain Hmox1 mRNA and protein expression were assessed by quantitative RT-PCR and Western blotting, respectively. Hmox1 mRNA is shown as mean number of Hmox1 per HPRT mRNA molecules ± SD (n = 3 per group). (C) Bone marrow–derived DCs were purified (>98% CD11c+) and exposed to CoPPIX (50 μM for 16 hours) as in B. HO-1 (green) and CD11c (red) were detected as in A. Original magnification, ×400. (D) Expression of HO-1 was detected by Western blot in purified DCs shown in C. **P < 0.01; ***P < 0.001.

CO contributes to the protective effects of HO-1, as exposure of Hmox1−/− mice to CO mimicked the protective effects of HO-1 (Figure 1F, Figure 4, C and D, Figure 6B, and Figure 7B). One would expect, however, that other end products of heme degradation, e.g., biliverdin, may act in a similar manner (30). However, biliverdin does not suppress myelin-reactive Th cell proliferation, nor does it suppress EAE progression (Supplemental Figure 7).

One possible explanation may be that the protective effect of HO-1 is exerted within the CNS, which biliverdin cannot enter because of its exclusion by the blood-brain barrier.

Our data suggest that the mechanism underlying the protective effect of HO-1 is associated with a profound inhibition of leukocyte accumulation (Figure 2G and Figure 3A) and reactivation (Figure 3, B and C) within the CNS. This is suggested by the observation that HO-1 induction by CoPPIX administration after EAE onset reduced the number of inflammatory foci (Figure 2G) as well as the total number of CNS Th cells, CD8+ T cells, and Mφ (Figure 3A) and in addition suppressed the proliferation of the remaining Th and CD8+ T cells (Figure 3, B and C) infiltrating the CNS.

The antiproliferative effect of HO-1 was shown in vitro to be strictly dependent on DCs (Figure 4G) that express high levels of HO-1 (Figure 5, B and C). That a similar effect may occur in vivo to arrest EAE progression is suggested by the observation that DCs expressing high levels of HO-1 were detected in the CNS of CoPPIX-treated mice in which EAE progression was arrested (Figure 5A).

Induction of HO-1 leads to specific inhibition of MHC class II in APCs, including DCs (Figure 6, A and B), microglia (Figure 6C), and CNS-infiltrating Mφ (Figure 6D). Induction of HO-1 expression in microglia suppresses STAT-1 phosphorylation as well as CIITA expression, 2 critical events for MHC class II expression in APCs (28) (reviewed in ref. 29) as well as in the reactivation of myelin-reactive Th cells in the CNS (31). This effect is likely to contribute to the overall protective effect of HO-1 induction, as MHC class II expression in microglia is thought to be involved in EAE pathogenesis and progression (reviewed in refs. 32, 33).

That inhibition of MHC class II accounts for the protective effect of HO-1 is supported by the association between certain human MHC class II locus alleles and MS susceptibility (reviewed in ref. 34). Moreover, peptides that interfere directly with MHC class II–mediated antigen presentation to myelin-reactive Th cells are very efficient in arresting EAE progression (35) (reviewed in ref. 2), suggesting again that inhibition of MHC class II expression.

Figure 5

CoPPIX induces HO-1 expression in DCs in vivo and in vitro. (A) C57BL/6 mice were randomized 2 days after EAE onset and treated daily with PBS, CoPPIX, or ZnPPIX. HO-1 and CD11c (DC) expression in spinal cords was detected by immunocytochemistry 7 days after beginning treatments and analyzed by confocal microscopy. Shown are HO-1 (left panels), CD11c (middle panels) and CD11c plus HO-1 (right panels). Original magnification, ×240. Arrows indicate positive staining. (B) Unsorted bone marrow–derived DCs (approximately 80% CD11c+) were exposed to CoPPIX or ZnPPIX, and Hmox1 mRNA and protein expression were assessed by quantitative RT-PCR and Western blotting, respectively. Hmox1 mRNA is shown as mean number of Hmox1 per HPRT mRNA molecules ± SD (n = 3 per group). (C) Bone marrow–derived DCs were purified (>98% CD11c+) and exposed to CoPPIX (50 μM for 16 hours) as in B. HO-1 (green) and CD11c (red) were detected as in A. Original magnification, ×400. (D) Expression of HO-1 was detected by Western blot in purified DCs shown in C. **P < 0.01; ***P < 0.001.

expression in the transciptional regulation MHC class II expression in APCs (28) (reviewed in ref. 29), the inhibitory effect of HO-1 over MHC II expression in these cells might be explained by its ability to suppress STAT-1 phosphorylation and CIITA expression.
by APCs is probably sufficient to explain the protective effects of HO-1 observed herein. Another possibility would be that HO-1 promotes the accumulation of regulatory T cells and/or their activity within the CNS. This would be consistent with widespread evidence that regulatory T cells can control the pathogenesis of EAE (6, 36–38) as well as with the hypothesis that HO-1 expression may control regulatory T cell function (39). However, we observed that despite its ability to suppress ongoing EAE, induction of HO-1 failed to modulate the number of CNS-infiltrating regulatory T cells (Figure 3B). Furthermore, we also found that the number and function of regulatory T cells was unaffected in naive Hmox1−/− mice compared with Hmox1+/+ controls, suggesting that HO-1 does not influence regulatory T cell development and/or function (40). Taken together, these data suggest that the protective effect of HO-1 in EAE does not act via modulation of regulatory T cells.

That HO-1 exerts its protective effects via APCs, including CNS microglia (Figure 6, C and D), is relevant for its mechanism of action if one considers that immunomodulation within the CNS is probably required to arrest MS progression. This may explain the relative lack of efficiency in treating MS by controlling exclusively peripheral antigen presentation, which is probably not as relevant, whereas prevention of effector Th cell reactivation by CNS APCs almost certainly is (26, 31). Our finding that induction of HO-1 after EAE onset suppressed Th cell reactivation and effector function within the CNS (Figure 4B) may explain why this approach was effective in suppressing disease progression (Figure 1, B and C, and Table 2).

Our present data suggest that upon induction of HO-1 in APCs, the effector function of myelin-reactive Th cells in the CNS is modulated in a manner that suppresses their pathogenicity. This is supported by the suppression of neuroinflammation, i.e., IFN-γ, but not neuroprotective, i.e., IL-10 (41) and TNF-α (42), cytokine expression by CNS-infiltrating Th cells (Figure 3B). Presumably, inhibition of high-level IFN-γ expression by CNS-infiltrating Th cells should promote oligodendrogenesis and thus aid to EAE remission (43). It should be noted, however, that while inhib...
bition of IFN-γ expression in CNS-infiltrating Th cells is likely to contribute to EAE regression (44), this remains to be formally established as EAE is exacerbated in IFN-γ-deficient mice (45).

One possibility not excluded by the present study is that HO-1 may prevent EAE progression not only by immunomodulation but also by its cytoprotective properties (46, 47) in the CNS, i.e., oligodendrocytes or neurons (48). Such an effect would be consistent with the observed arrest of EAE progression (49) as well as with our previous observation that cytoprotection afforded by HO-1 can prevent the rejection of transplanted organs (50).

Even with the caution necessary for extrapolating from EAE to MS, there are several independent lines of evidence suggesting that HO-1 expression affects the clinical outcome of MS. First, HO-1 is expressed in the CNS of MS patients (9). Second, HO-1 prevents the deleterious effects of inflammation in humans (51). Third, a (GT)n microsatellite polymorphism in the human HMOX1 promoter controls HO-1 inducibility and dictates the incidence of several inflammatory diseases (reviewed in ref. 52). Additional studies are needed to determine whether HO-1 functions to prevent MS progression or promote its remission.

In conclusion, we found that HO-1 suppresses the pathologic outcome of autoimmune neuroinflammation associated with the development of EAE. This effect is mediated at least in part by CO, which acts on APCs to inhibit the expression of MHC class II and presumably the reactivation of pathogenic Th cells within the CNS. We suggest that modulation of HO-1 expression or administration of CO may be a useful therapeutic strategy to treat MS patients.

**Methods**

**Animals.** C57BL/6 and SJL/J mice were maintained under specific pathogen-free conditions approved by the Animal User and Institutional Ethical Comities of the Instituto Gulbenkian de Ciencia and the Beckman Center for Molecular Medicine. Mice were used between 6 and 8 weeks of age. Hmox1−/− mice were originally generated by S.-F. Yet (Brigham and Women’s Hospital, Boston, Massachusetts, USA; ref. 53). Littermate Hmox1+/− and Hmox1+/+ mice were used as controls.

**Cells and reagents.** Microglial BV2 cells, obtained from E. Blasi (University of Modena and Reggio Emilia, Modena, Italy), were cultured essentially as described previously (54). Recombinant mouse IFN-γ (ProteoTech) was used to induce MHC class II expression in BV2 cells. MOG35−55 was synthesized at the Biopolymers Laboratory of Harvard Medical School. PLP19−21 was synthesized at the PAN Facility of the Beckman Center for Molecular and Cellular Medicine. CoPPIX, ZnPPIX (Frontier Scientific Inc.), and biliverdin hydrochloride (MP Biomedicals) were dissolved in 0.2 N NaOH, neutralized with 0.2 N HCl, adjusted to 1 mg/ml (CoPPIX and ZnPPIX) and 10 mM (biliverdin) with distilled water, and sterilized by filtration.

**Cytokine assays.** Cell culture supernatants were used to measure TNF-α, IFN-γ, and IL-12/23(p40) concentrations by ELISA according to the manufacturer’s indications (OptEIA; BD Biosciences — Pharmingen).

**CNS leukocyte infiltration.** Leukocytes were isolated from the CNS as described previously (55). The total number of CD45+ cells, CD11b+, CD4+, and CD8+ T cells in the CNS was assessed by flow cytometry, using a fixed number of latex beads (Beckman Coulter) coacervated with a preestablished volume of the cellular suspensions.

**DCs.** Bone marrow from naive mice was flushed, and single-cell suspensions were cultured (37°C, 5% CO2, 95% humidity) in RPMI 1640 (Invitrogen), 2 mM l-glutamine (Sigma-Aldrich), 100 U/ml penicillin, 100 μg/ml streptomycin (all from Invitrogen), and 1% GM-CSF conditioned medium. Medium was replaced every 48 hours until day 6 of culture, after which CD11c+ cells were purified as described above or remained untreated.

**Flow cytometry and antibodies.** Surface markers and intracellular cytokines were detected essentially as described previously (55). Purified anti-mouse CD4 (RM4–5), CD8 (YTS169.4), CD11b (M1/70), CD11c (HL3), CD40 (3/23), CD45 (30-F11), CD80 (16-10A1), CD86 (GL1), R220 (RA3-6B2), IA−/− (AF6–120.1), IL-2 (JES6–5H4), IL-10 (JES5–16E3), TNF-α (MP6–XT22), and IFN-γ (XM1G12; all BD Biosciences — Pharmingen) were used. Anti-FcyRIII/II receptor mAbs were prepared in house from hybridoma (2.4G2) culture supernatants. Antibodies were directly conjugated to PE, allophycocyanin, or FITC.

**In vivo BrdU incorporation.** Mice received BrdU (50 μg/g body weight i.p., administered 4 times every 2 hours; BD Biosciences — Pharmingen). CNS leukocyte infiltrates were isolated as described above, and nuclear BrdU was detected using the FITC-labeled anti-BrdU Flow Kit according to the manufacturer’s indications (BD Biosciences — Pharmingen).

**Leukocyte isolation and purification.** Draining lymph node cells were homogenized into single-cell suspension. CD4+ and CD11c+ cells were purified using single-step anti-CD4 (L3T4) and anti-CD11c (N418) MicroBeads, respectively (Miltenyi Biotec). CD8+ and CD19+ cells were purified by 2-step labeling consisting of FITC-labeled anti-CD8 (SK1) and anti-CD19 (4G7) mAb (BD) followed by anti-FITC–conjugated MicroBeads (Miltenyi Biotec). Cells were separated using a MidiMACS magnetic isolation system (Miltenyi Biotec) and purity was assessed by flow cytometry.

**MOG35–55-reactive T cell proliferation.** Draining lymph node cells were isolated from PBS-, CoPPIX-, or ZnPPIX-treated animals 8 days after footpad immunization (MOG35–55 plus CFA). Cells were plated in 96-well microtiter plates (5 × 104 cells per well) in RPMI 1640 (Invitrogen), 2 mM l-glutamine (Sigma-Aldrich), 100 U/ml penicillin, 100 μg/ml streptomycin, 10% FCS, 50 μM 2-mercaptoethanol (2-ME), 10 mM HEPES, and 1 mM sodium pyruvate (all from Invitrogen) and exposed to MOG35–55 (10 μg/ml) or concanavalin A (2 μg/ml; Sigma-Aldrich) for 72 hours at 37°C (5% CO2, 95% humidity). Cell proliferation was assessed by [3H]thymidine (1 μCi/well, GE Healthcare) incorporation during the last 6 hours of culture evaluated in a scintillation counter (Tomtec; Pharmacia).

**Immunohistochemistry.** Purified bone marrow–derived DCs were plated in glass coverslips (Paul Marienfeld GmbH & Co.) and fixed in acetone (10 minutes at −20°C). Rabbit anti–HO-1 polyclonal antibody (SPA895, Stressgen Biotechnologies), PE-labeled anti-CD11c mAb (HL3; BD Biosciences — Pharmingen) and FITC-labeled goat anti-rabbit polyclonal antibody (Sigma-Aldrich) were used. Slides were mounted in VECTASHIELD (Vector Laboratories), and fluorescence was detected by confocal microscopy (Leica Spectral TCS-SP2; Leica Microsystems). Images were acquired using Leica confocal software (version 2.61).

**Histology.** Mice were perfused with PBS followed by 10% formalin. Brain and spinal cord sections were embedded in paraffin and stained with hematoxylin and eosin or with Luxol fast blue stains, and inflammatory foci were enumerated in meninges and parenchyma as described previously (56).

**Immunohistology.** Mice were perfused with PBS, and their spinal cords were harvested, embedded in Tissue-Tek OCT (Sakura), and snap-frozen in liquid nitrogen. Spinal cord sections (10 μm) were fixed in acetone, and antigen detection was performed essentially as described previously (47).
Rabbit anti-HO-1 polyclonal antibody (SPA895; Stressgen Biotechnologies), biotin-labeled anti-MHC class II mAb (AF6-120.1; BD Biosciences — Phar mergen), PE-labeled anti-CD11c mAb (HL3; BD Biosciences — Pharamgen), and FITC-labeled goat anti-rabbit (Sigma-Aldrich) polyclonal antibody were used. HRP-conjugated streptavidin and Vectastain Elite ABC kit were used according to the manufacturer’s instructions (Vector Laboratories). HRP stainings were revealed using 3,3-diamenobenzidine (Sigma-Aldrich), and tissues were counterstained with Harris hematoxylin (Sigma-Aldrich). Images were acquired using a Leica (DM LB2) microscope (Leica Microsystems) equipped with an Evolution MPS.0 color camera (Media Cybernetics) and free-GIMP 2.2.10 software (http://portableapps. com/apps/graphics_pictures/gimp_portable). Fluorescence staining was detected and processed as described above.

CO exposure. Mice were placed in a plexiglass gait chamber (60x100x100 cm) and exposed continuously to CO as described previously (47). Cells (37 °C, 95% humidity) were exposed to CO (250 ppm in air, 5% CO2) in a plexiglass gait chamber (2 l/min). CO concentration was monitored using a CO analyzer (Interscan Corporation). Air controls were maintained in a similar chamber without CO.

Western blots and antibodies. Western blots were performed as described previously (46, 47) using anti-HO-1 (SPA986; Stressgen Biotechnologies), anti–STAT-1 (Upstate USA Inc.), and anti–phospho–STAT-1 (Upstate USA Inc.) rabbit polyclonal antibodies as well as anti–β-tubulin (Sigma-Aldrich) and anti–β-actin (Sigma-Aldrich) mouse mAbs. HRP-labeled goat anti-rabbit (31460; Pierce Biotechnology) or goat anti-mouse (31439; Pierce Biotechnology) polyclonal antibodies were used to detect the primary antibodies. HRP activity was revealed using ECL. Images were acquired using a Kodak 440CF image station.

Real-time PCR. Total RNA was extracted using RNeasy Protect Mini Kit (QIAGEN) according to the manufacturer’s instructions and reverse transcribed as described previously (22). HO-1 (5′-TCTCAGGGGGT-CAGGTC-3′ and 5′-GGAGCGGTGTCTGGGATG-3′, CIITA (5′-CTC- TACACCTCTATGACC-3′ and 5′-GCTTCTGCTCCTGCTTCTAC-3′), and hypoxanthine-guanine phosphoribosyltransferase (HPRT; 5′-GTT-GGATACGGCCAGCTTGTG-3′ and 5′-GATTCACCTTGCGCTAT- CATCTTAGGC-3′) PCR products were detected using LightCycler real-time quantitative PCR (Roche Diagnostics) as described previously (22). Statistics. Significance of clinical scores significance was examined by the Mann-Whitney test. Significance of Hmox1−/− versus Hmox1+/+ mouse survival was examined by the log-rank test. Fisher’s exact test was used for analyses of disease remission. All other statistical analyses were performed using ANOVA with Bonferroni’s correction for multiple comparisons. P < 0.05 was considered significant in all tests.

Acknowledgments

This work was supported primarily by a GEMI Fund AgaLinde Healthcare grant to M. Soares. Â. Chora, A. Cunha, and T.F. Pais were supported by fellowships BD/3106/2000, SFRH/BD/21558/2005, and SFRH/BPD/5554/2001, respectively, from Fundação para a Ciência e Tecnologia. R.A. Sobel was supported by NIH grant NS 046414. The authors thank Abdel Saoudi (Institut National de la Sainte et de la Recherche Medicale) for essential input at the initial phase of this project and Fritz H. Bach (Harvard Medical School), Jocelyne Demengeot (Instituto Gulbenkian de Ciência), and Santiago Zelenay (Instituto Gulbenkian de Ciência) for critical reading of the manuscript. We also wish to thank Nuno Sepúlveda and Ana Cristina Paulo for support with statistical analysis, Sofia Rebelo for excellent technical support, António Sousa for building the CO exposure chambers, and Mark P. Seldon for setting up and advising with CO exposure.
