Increased cap-dependent mRNA translation rates are frequently observed in human cancers. Mechanistically, many human tumors often upregulate the cap binding protein eukaryotic translation initiation factor 4E (eIF4E), leading to enhanced translation of numerous tumor-promoting genes. In this issue of the JCI, Graff and colleagues describe potent antitumor effects using second-generation antisense oligonucleotides for eIF4E (see the related article beginning on page 2638). If their results are recapitulated in a clinical setting, this strategy will provide a promising antitumor therapy with broad-reaching applications.

Protein synthesis is required for many critical cellular processes, and cells regulate mRNA translation rates according to their needs. Interestingly, dysregulated translation has now been linked to multiple human cancers (1, 2). Increased translation rates lead to an overproduction of proteins involved in proliferation, survival, metastasis, and other malignant characteristics (3–5). Protein synthesis regulation is complex, and its alteration in tumor cells occurs at numerous points. Many tumor-promoting mechanisms ultimately cause the activation of a critical regulator of cap-dependent translation, the eukaryotic translation initiation factor 4F (eIF4F) complex. Numerous human tumors exhibit inappropriate eIF4F activation, including lymphomas and breast, prostate, colorectal, head and neck, cervical, bladder, and lung cancers (3). Therefore, therapeutically targeting eIF4F activity is exceedingly attractive, as it would potentially be applicable to a broad range of human cancers. In this issue of the JCI, Graff and colleagues (6) report such a strategy, attacking one of the important components of eIF4F, eIF4E, with striking efficacy in tumor models. If this treatment is successful in the clinic, it holds great promise for use against many human tumors and may be especially effective if used in combination with more traditional chemotherapy treatments.

Cap-dependent protein synthesis and its regulation

To provide better insight into the underlying mechanism for this therapy and why it might ultimately be so effective against...
its availability limits translation initiation rates, and therefore translation itself. Free elf4E levels are determined primarily by their degree of association with a class of regulatory proteins termed elf4E binding proteins (4E-BPs). 4E-BPs bind to elf4E at the elf4G binding site and therefore block elf4F assembly by sequestering its rate-limiting member. The 4E-BPs (there are three family members) are regulated in turn by phosphorylation at several sites, with increased phosphorylation leading to decreased elf4E binding capacity. 4E-BP phosphorylation is carried out primarily by the mammalian target of rapamycin complex 1 (mTORC1) (8). mTORC1 gathers information about the cellular environment, including nutrient, growth factor, and oxygen availability and activates downstream effectors accordingly (2, 9). mTORC1 phosphorylates two key substrates, p70S6K, whose activity mediates the binding of several key initiation factors (10), and 4E-BPs. This way, mTORC1 integrates the richness of the environment with biosynthetic pathways downstream, dictating whether cells will grow and proliferate. Importantly, key points in the pathway that activate mTORC1 are frequently mutated in human cancers. For example, PI3K activity is often high in tumors due to the loss of the PTEN tumor suppressor, which allows a constitutive activation of the AKT kinase, inappropriate mTORC1 signaling, and constitutive phosphorylation and inactivation of 4E-BPs (2). Due to the important role of mTORC1 in cell growth and proliferation, multiple mTORC1 inhibitors are progressing through clinical trials.

eIF4E availability dictates not only the rate of protein synthesis but, perhaps more importantly, its quality. It has been proposed that the mRNA 5′ untranslated region (5′UTR) structure in part dictates translation efficiency (reviewed in ref. 3). mRNAs with highly complex 5′UTR structures ("weak" mRNAs) are more difficult to translate than those with relatively uncomplicated structures ("strong" mRNAs). This model postulates that strong mRNAs are translated at a relatively constant rate with little impact from active initiation factor availability. Conversely, because weak mRNAs must compete for elf4E binding and retention, they are translated much more efficiently when elf4E is present in excess. Importantly, weak mRNAs tend to be those with roles in proliferation (cyclin D1, c-Myc, and ornithine decarboxylase), survival (Bcl-xL, etc.), angiogenesis (VEGF,
basic FGF, and HIF-1α), and other malignancy-promoting functions (MMP9, etc.) (3). Therefore, targeting elf4E would allow the clinician to hit a variety of gene targets with one therapy, since increased translation rates alter the expression of a variety of genes. In addition, targeting an essential component of translation initiation at a point far downstream should allow little chance of escape via activating upstream components of the pathway. However, as attractive as this strategy is, little success has followed attempts to therapeutically attack the elf4E complex. First, because elf4E function is dictated by protein-protein interactions and mRNA binding, complex disruption has proven to be extremely difficult. Additionally, the potential off-target effects of eliminating an essential component of the translation machinery are troubling. Graff et al. (6) report the use of second-generation antisense oligonucleotides (ASOs) to effectively downregulate elf4E in tumors, greatly attenuating tumor growth in breast and prostate cancer models. In addition, and perhaps surprisingly, no toxicity was detected using this strategy. These results raise the possibility of effectively attacking protein translation downstream of mTORC1 in the clinic.

**Effects of elf4E downregulation in tumors and other tissues**

The use of elf4E ASOs was previously shown to have the predicted effect of reversing transformation (11, 12). However, this strategy was not generally effective due to the difficulties of using ASOs therapeutically. Graff and colleagues (6) utilized second-generation ASOs, which are modified to enhance their tissue half-life. They show that treatment of cells in culture with these oligonucleotides caused a significant decrease in elf4E expression, leading to decreased expression of cyclin D1 and VEGF (both elf4E translational targets), without a drop in global protein synthesis. They also demonstrated cytotoxicity in vitro, an important observation in light of the potential antitumor effects of elf4E ASOs. The most interesting data, however, were generated in vivo: mice with subcutaneous xenograft tumors were treated with elf4E ASOs, causing a profound reduction in tumor growth. Elf4E ASO administration resulted in an approximately 50% decrease in elf4E levels within tumors. This level of downregulation almost completely prevented tumor growth, whereas tumors in control-treated mice continued to grow. In addition, treatment with elf4E ASOs downregulated tumor VEGF levels and decreased the overall vessel number within the tumors. The authors then addressed an important question: the potential systemic toxicity that elf4E downregulation might be predicted to cause. Strikingly, despite a highly significant downregulation (approximately 70%) of elf4E in the liver, there was no overall toxicity and no negative effects on liver transaminase levels. It is perhaps somewhat surprising that such a substantial decrease in elf4E abundance does not negatively impact liver function. Since most housekeeping genes are strong mRNAs, however, low elf4E levels might be sufficient to translate them (Figure 1). This is a critically important point for the future use and efficacy of elf4E ASOs, and more testing is certainly in progress to assess its overall effects.

### The promises and questions of elf4E therapy in human tumors

The results presented by Graff et al. (6) are very exciting for human tumor treatment. Some questions remain, however, and must be addressed as this strategy moves forward. It will be necessary to further examine mechanisms of elf4E ASO function. Clearly, treating cells in vitro with elf4E ASO induced apoptosis. It is likely that treatment in vivo also causes apoptosis, though this will have to be more carefully examined. Tumors treated with elf4E ASO did not grow, but neither did they regress, essentially remaining the same size. It will be necessary to determine whether elf4E ASOs act cytotoxically or cytostatically. It is possible that elf4E ASOs do not reach a high enough concentration in the xenografts to cause the level of cell death observed in vitro. Alternatively, lowering elf4E levels in these tumors might simply arrest proliferation. This will be an important point, as the ultimate goal of tumor therapy is the death of tumor cells. If elf4E ASOs act cytotoxically or cytostatically, their use as single-agent therapies might be limited. However, an approach that could be highly productive might combine elf4E ASOs with traditional cytotoxic chemotherapeutics. This drug combination would be especially effective if elf4E ASO treatment lowers the tumor cell apoptotic threshold. In conjunction, these agents together would likely induce massive tumor cell apoptosis.

The ability to treat tumors exhibiting high elf4E levels is very exciting for several reasons. First, as mentioned above, many tumors have been described in which elf4E is overexpressed (Figure 1), potentially promising broad application. Furthermore, many tumors, such as PTEN, have mutations in upstream components of the pathway that ultimately regulate elf4E, and such tumors should be susceptible to therapy aimed downstream of these components. Second, small increases in elf4E expression have profound effects on tumor promotion (13), increasing the likelihood of elf4E ASO efficacy. Third, it is known that elf4E overexpression results in resistance to rapamycin (14, 15) and rapamycin/chemotherapy combination (16), so this treatment would offer an alternative for patients with rapamycin-resistant tumors. This excitement is not without caveats however. It is also possible that combination therapy (or elf4E ASO treatment alone) could lower the apoptotic threshold in certain normal tissues. In this scenario, lowering elf4E levels would have a profoundly deleterious impact on tissues such as the liver, among others, complicating the dosage and benefit. In addition, immune system effects will have to be assessed: multiple immune responses require massive cell proliferation and production of soluble mediators that naturally require the synthesis of new proteins. Thus severely decreasing systemic elf4E levels might also be detrimental to immune function. Indeed rapamycin, which should inhibit elf4E activity, was originally used as an immunosuppressive agent, and as such, elf4E downregulation may have an impact on the efficacy of the immune response. Graff and colleagues assessed splenic mass, which was not changed relative to controls, although these parameters will need to be examined in actively proliferating cells such as those responding to an infection.

**Summary and future directions**

Despite these potential hurdles, the data presented by Graff et al. (6) offer exciting and broad-reaching potential for the treatment of many forms of human cancer. Future experiments must address the mechanism(s) by which elf4E ASOs function. Additionally, potential off-target effects must be assessed, especially in situations in which tissues are stressed or must proliferate. However, this approach holds great promise: attacking the elf4E complex has been recognized as a potentially excellent therapeutic approach for some time. The difficulty in disrupting this complex therapeutically has made it unproductive in the clinic so far. With the
development of second-generation ASOs for eIF4E, Graff and colleagues may enable us to finally target this important complex effectively, providing a potentially wide-ranging antitumor modality.

Two tales concerning skeletal muscle

David J. Glass

Novartis Institutes for BioMedical Research, Cambridge, Massachusetts, USA.

It was previously appreciated that the determination of skeletal muscle fiber type (fast or slow) could be regulated by class II histone deacetylases (HDACs), which function by inhibiting the transcription factor myocyte enhancer factor 2 (MEF2). In a report by Potthoff et al. in this issue of the JCI, it is further shown that HDACs are degraded via the ubiquitin/proteasome pathway, opening up a search for the putative E3 ligase that mediates the proteolysis of the responsible HDACs (see the related article beginning on page 2459). In a second report, by Suzuki et al., a new convergence between the biology of muscular dystrophy and muscle atrophy is elucidated (see the related study beginning on page 2468). It had previously been known that NO signaling is dysregulated during muscular dystrophy due to the disruption of the dystrophin glycoprotein complex (DGC), which anchors neuronal NOS (nNOS). Here it is shown that nNOS is similarly perturbed in a setting of skeletal muscle atrophy. Both of these studies suggest new avenues for the treatment of skeletal muscle disease.

Ubiquitination of class II HDACs determines slow–versus fast–muscle fiber type

To the uninitiated, muscle may appear to be homogeneous, but in fact it is composed of distinct fiber types, referred to as slow and fast, defined by the myosin iso-type expressed in the particular fiber (slow muscle expresses type I myosin; fast fibers can express types IIa, IIb, and IIX) and by the oxidative enzymes that are coexpressed in slow muscle. The variety in fiber type enables the animal to perform different types of work. It had previously been shown that fiber type could be perturbed by class II histone deacetylases (HDACs), which act by repressing the transcription factor myocyte enhancer factor 2 (MEF2), which in turn is required for the transcription of the oxidative genes found in slow fibers (Figure 1) (1). In a study published in this issue, Potthoff et al. (2) demonstrate that class II HDACs are regulated posttranscriptionally, apparently by the ubiquitin/proteasome pathway, despite being transcribed in soleus muscle, HDAC4 and HDAC5 protein levels were not observed there. However, when mice were treated with an inhibitor of the proteasome — the pharmacologic agent MG132 — an accumulation of HDACs in the soleus muscle was observed. Further, in these experiments on mice, ubiquitinated HDAC species could be isolated from the nuclear fraction of soleus muscle. Thus, in slow but not fast muscle fibers, there is a dearth of HDAC4 and -5 proteins, allowing MEF2 to activate the slow-muscle program (Figure 1).

In the Potthoff et al. study, it was not possible to identify a particular class II HDAC as being necessary and sufficient to regulate MEF2 (2). Studies with knockout animals revealed that HDAC4, -5, and -9 were able to compensate for each other’s absence. It was only when double- and triple-knockout animals were employed that a clear fiber-type switch, from fast to slow, was observed (though an HDAC4, -5, -9 triple-knockout animal was not able to improve on the 80% slow-fiber composition observed in HDAC4, -5 and HDAC5, -9 double knockouts, perhaps indicating that in some fibers there may be more heterogeneity).
