Fibroblasts, which are the most numerous cell type in the heart, interact with cardiomyocytes in vitro and affect their function; however, they are considered to play a secondary role in cardiac hypertrophy and failure. Here we have shown that cardiac fibroblasts are essential for the protective and hypertrophic myocardial responses to pressure overload in vivo in mice. Haploinsufficiency of the transcription factor–encoding gene Krüppel-like factor 5 (Klf5) suppressed cardiac fibrosis and hypertrophy elicited by moderate-intensity pressure overload, whereas cardiomyocyte-specific Klf5 deletion did not alter the hypertrophic responses. By contrast, cardiac fibroblast–specific Klf5 deletion ameliorated cardiac hypertrophy and fibrosis, indicating that KLF5 in fibroblasts is important for the response to pressure overload and that cardiac fibroblasts are required for cardiomyocyte hypertrophy. High-intensity pressure overload caused severe heart failure and early death in mice with Klf5-null fibroblasts. KLF5 transactivated Igf1 in cardiac fibroblasts, and IGF-1 subsequently acted in a paracrine fashion to induce hypertrophic responses in cardiomyocytes. Igf1 induction was essential for cardioprotective responses, as administration of a peptide inhibitor of IGF-1 severely exacerbated heart failure induced by high-intensity pressure overload. Thus, cardiac fibroblasts play a pivotal role in the myocardial adaptive response to pressure overload, and this role is partly controlled by KLF5. Modulation of cardiac fibroblast function may provide a novel strategy for treating heart failure, with KLF5 serving as an attractive target.

Introduction
Myocardial hypertrophy is an essential adaptive process through which the heart responds to various mechanophysical, metabolic, and genetic stresses. However, the hypertrophy induced by sustained overload eventually leads to contractile dysfunction and heart failure through mechanisms that remain poorly understood (1). In addition to enlargement of individual cardiomyocytes, the hypertrophied myocardium exhibits complex structural remodeling that involves rearrangement of the muscle fibers, interstitial fibrosis, accumulation of extracellular matrix, and angiogenesis (2, 3), which implies that the non-muscle cells residing in the interstitium likely play important roles in both cardiac hypertrophy and heart failure. In fact, cells other than cardiomyocytes account for approximately 70% of the total cell number in the heart, with the majority being fibroblasts (4, 5). In addition to extracellular matrix proteins (e.g., collagens), cardiac fibroblasts produce a variety of growth factors that likely mediate an interplay between cardiac fibroblasts and cardiomyocytes. For instance, several humoral factors secreted by cardiac fibroblasts, including cardiotoxin-1 (6), endothelin-1 (7), IL-6 (8), periostin (POSTN) (9), and leukemia inhibitory factor (10), have been shown to induce hypertrophic responses in cultured cardiomyocytes. Cardiac fibroblasts also promote proliferation of cardiomyocytes through paracrine interactions in developing hearts (11). And very recently it was shown that inhibition of a fibroblast-selective miRNA ameliorated cardiac fibrosis, hypertrophy, and dysfunction, suggesting that fibroblasts play a detrimental role in cardiac remodeling (12). Still, the precise function of cardiac fibroblasts during adaptive responses of the myocardium remains unclear (2).

Members of the Krüppel-like factor (KLF) family of transcription factors are important regulators of development, cellular differentiation and growth, and the pathogenesis of various diseases, including cancer and cardiovascular disease (13). We previously used Klf5–/– mice to show that KLF5 is required for cardiac hypertrophy and fibrosis in response to continuous infusion of angiotensin II (AII) (14, 15). In primary cultured cardiac fibroblasts, KLF5 directly controls transcription of Pdgfa, encoding platelet-derived growth factor A (PDGF-A) (14), which is known to be involved in tissue remodeling and wound healing (16–19). The precise role played by KLF5 in cardiac hypertrophy and heart failure remains unclear, however.

In the present study, we developed conditional Klf5-knockout mouse lines to examine the cell type–specific functions of KLF5 in cardiac hypertrophy and heart failure. While cardiomyocyte–specific deletion of Klf5 did not alter the hypertrophic responses
KLF5 was increased by LI-TAC (Supplemental Figure 3) and that cardiac expression of KLF5 plays an important role in pressure overload–induced cardiac hypertrophy. To analyze KLF5’s function in cardiac adaptive responses, we first established models of pressure overload–induced cardiac hypertrophy using transverse aortic constriction (TAC).

By applying a low-intensity TAC (LI-TAC) for 2 weeks, we were able to induce cardiac hypertrophy with preserved cardiac systolic function, while application of high-intensity TAC (HI-TAC) induced severe myocardial dysfunction and LV dilation (Supplemental Figure 3A, C). Thus KLF5 appears to play a critical role in pressure overload–induced cardiac hypertrophy and fibrosis.

Cardiac fibroblast–specific deletion of Klf5 does not affect pressure overload–induced cardiac hypertrophy. When we examined the involvement of KLF5 in cardiac hypertrophy using the LI-TAC model, we found that cardiac expression of KLF5 was increased by LI-TAC (Supplemental Figure 3) and that LI-TAC–induced cardiac hypertrophy and fibrosis was diminished in Klf5+/– mice (Figure 1 and Supplemental Figure 4). Moreover, expression of 4 fibrosis-related genes, ColIa1, Fln1, Ctgf, and Spp1, was significantly suppressed in Klf5+/– hearts (Supplemental Figure 4). Thus KLF5 appears to play a critical role in pressure overload–induced cardiac hypertrophy and fibrosis.

KLF5 plays an important role in pressure overload–induced cardiac hypertrophy. To analyze KLF5’s function in cardiac adaptive responses, we first established models of pressure overload–induced cardiac hypertrophy using transverse aortic constriction (TAC). By applying a low-intensity TAC (LI-TAC) for 2 weeks, we were able to induce cardiac hypertrophy with preserved cardiac systolic function, while application of high-intensity TAC (HI-TAC) induced severe myocardial dysfunction and LV dilation (Supplemental Figures 1 and 2; supplemental material available online with this article; doi:10.1172/JCI44295S1). The survival rates in the LI- and HI-TAC groups were 100% and 90%, respectively, after 2 weeks, which suggests that the LI-TAC model induces adaptive hypertrophy, while in the HI-TAC model, the adaptive response fails to protect against the severe pressure overload and enable maintenance of cardiac function.

When we examined the involvement of KLF5 in cardiac hypertrophy using the LI-TAC model, we found that cardiac expression of KLF5 was increased by LI-TAC (Supplemental Figure 3) and that KLF5 is essential for pressure overload–induced hypertrophy. (A–D) Klf5+/– and wild-type mice were subjected to LI-TAC or sham operation. (A) Representative low-magnification views of H&E-stained heart sections from WT and Klf5+/– mice 2 weeks after the operations. Scale bar: 1 mm. (B) Heart weight/body weight ratios (B) and relative cross-sectional areas of cardiomyocytes (C) from wild-type and Klf5+/– hearts. (D) Fractional areas of fibrosis in cross sections of hearts as determined by elastic picrosirius red staining. *P < 0.01 versus sham control of the same genotype; *P < 0.05 versus wild-type subjected to TAC. n = 7. (E) Expression of KLF5 in normal and hypertrophied hearts 4 days after LI-TAC. Cells were double stained for KLF5 (brown) and a cardiomyocyte marker, αMHC (red); nuclei were counterstained in blue. Scale bar: 20 μm.
normal or pathological cardiomyocyte lineage (23), but is induced in cardiac fibroblasts by TAC (9, 24, 25). The activity of Cre recombinase in the Postn-Cre mice was examined after they were crossed with R26RstoplacZ indicator mice (26). Although only a few β-galactosidase+ cells were found in the heart under basal conditions, LI-TAC induced robust lacZ expression in fibrotic areas in hearts from R26RstoplacZ;Postn-Cre mice (Figure 3A and Supplemental Figure 8). As expected, lacZ expression was not detected in either cardiomyocytes or ECs (Supplemental Figure 8).

We then used flow cytometry to further analyze expression of β-galactosidase in populations enriched in either cardiomyocytes or non-myocytes isolated from R26RstoplacZ;Postn-Cre mice subjected to LI-TAC (Supplemental Figure 9). β-Galactosidase+ cells were not found in the cardiomyocyte population. Moreover, β-galactosidase+ cells isolated from the non-myocyte population expressed a fibroblast-specific marker, discoidin domain receptor 2 (Ddr2), but not the cardiomyocyte-specific marker αMHC (Myh6) or the endothelial marker VE-cadherin (Cdh5), which supports the notion that β-galactosidase+ cells are fibroblasts. Klf5+ cells were then bred with the Postn-Cre mice to generate Klf5fl/fl;Postn-Cre mice. These animals were born with no apparent abnormalities and were healthy into adulthood. To examine the efficacy of Cre-mediated deletion of Klf5 in each cell type, we isolated cardiomyocytes, cardiac fibroblasts, and ECs from adult mice. Cardiomyocytes were isolated using the Langendorff perfusion method (27). Fibroblasts and ECs were sorted from non-myocyte-enriched cell populations using anti-Thy1 antibody for fibroblasts (11, 28) and anti-CD31 for ECs. Because Thy1 is also expressed in T lymphocytes, CD3+ cells were analyzed for surface expression of Thy1 and CD31 (Figure 3B). When the mRNA expression of cell type–specific lineage markers was analyzed, Myh6 was found to be expressed only in cardiomyocytes, while Ddr2 was expressed only in Thy1+CD31+CD3– cells and Cdb5 only in Thy1+CD31–CD3– cells (Figure 3C), which indicates that Thy1+CD31+CD3– cells were fibroblasts. Approximately 72% of the Klf5 gene was deleted in Thy1+CD31+CD3– fibroblasts isolated from Klf5fl/fl;Postn-Cre mice subjected to LI-TAC for 2 weeks, whereas only 4% was deleted in the sham-operated mice (Figure 3D). No Klf5 deletion was observed in cardiomyocytes or ECs. Moreover, Cre mRNA was selectively expressed in Thy1– fibroblasts, as was endogenous Postn mRNA, which is consistent with fibroblast-specific Cre-mediated deletion by Postn-Cre (Supplemental Figure 10).

We further analyzed expression of Klf5 mRNA in each cell type in mice subjected to either the sham operation or LI-TAC (Figure 3E). In sham-operated hearts, levels of Klf5 expression were higher in Thy1– fibroblasts than in cardiomyocytes or ECs and did not differ between Klf5fl/fl and Klf5fl/fl;Postn-Cre mice. LI-TAC markedly increased Klf5 expression in fibroblasts (approximately 4-fold) and moderately increased it in cardiomyocytes in Klf5fl/fl mice. While Klf5 expression was clearly reduced in fibroblasts from Klf5fl/fl;Postn-Cre, as compared with Klf5fl/fl mice, it was not altered in cardiomyocytes, which is again consistent with fibroblast-specific deletion of Klf5.

LI-TAC induced less cardiac interstitial fibrosis in Klf5fl/fl;Postn-Cre mice than in control Klf5fl/fl mice, as expected (Figure 4, A–C), and expression of fibrosis-related factors such as Col1a1, Fn1, Ctgf, and Spp1 was reduced (Supplemental Figure 11A). In addition to fibrosis, increases in heart weight/body weight ratios, echocardiographic LV wall thickness, and cardiomyocyte cross-sectional area were smaller in Klf5fl/fl;Postn-Cre mice than Klf5fl/fl mice (Figure 4, D–F). Moreover, expression levels of hypertrophy-related genes such as Nppa, which encodes atrial natriuretic peptide (ANP), and Myb7, which encodes β–myosin heavy chain, were lower in Klf5fl/fl;Postn-Cre than Klf5fl/fl mice (Figure 4G), indicating suppression of hypertrophic responses. These phenotypes clearly demonstrate that not only is KLF5 expressed in cardiac fibroblasts essential for fibrosis, it is also important for mediating subsequent cardiomyocyte hypertrophy.

IGF-1 controlled by KLF5 mediates hypertrophic responses. We next investigated the mechanisms by which KLF5 expressed in fibroblasts controls hypertrophy of cardiomyocytes. Because earlier studies have suggested there are paracrine interactions between cardiomyocytes and fibroblasts (2, 3), we hypothesized that KLF5 might directly control the expression of paracrine factors in fibroblasts. To test that idea, we cultured cardiomyocytes in medium conditioned by cardiac fibroblasts transfected with either siRNA against KLF5 (29) or control siRNA (Figure 5A). We found that the medium conditioned by KLF5 knockdown fibroblasts was...
myocytes. Similarly, Thy1+ cardiac fibroblasts isolated from Klf5fl/fl;Pstn-Cre mice subjected to LI-TAC were less able to induce cardiomyocyte hypertrophy than Thy1+ cells from Klf5fl/fl mice (Supplemental Figure 12).

To identify the paracrine factor genes targeted by KLF5, we compared genome-wide gene expression profiles for the left ventricle in wild-type mice subjected to the sham operation and those subjected LI-TAC; and in Klf5fl/fl and Klf5fl/fl;Pstn-Cre mice subjected to LI-TAC (Supplemental Table 1). Thereafter, expression levels were verified by real-time PCR. We screened for genes encoding secreted proteins whose expression levels were significantly increased by LI-TAC in wild-type mice and were lower in Klf5fl/fl;Pstn-Cre than Klf5fl/fl mice. Among the 11 genes that met these criteria, 6 were preferentially expressed in cardiac fibroblasts, as compared with cardiomyocytes (Supplemental Table 1), and included 2 growth factor genes, Igf1 and Tgfb3, encoding IGF-1 and TGF-β3, and Pstn, encoding periostin. While knocking down KLF5 significantly reduced expression of Igf1 in cultured fibroblasts (Figure 6A), expression levels of Tgfb3 and Postn were not altered (Supplemental Figure 13), suggesting that KLF5 might directly control Igf1 expression. Moreover, Igf1 expression was highly enriched in fibroblasts (Figure 6B). IGF-1 reportedly promotes cardiac growth and improves cardiac function in patients with LV dysfunction and advanced heart failure (30–32). We therefore further analyzed Igf1 as a likely downstream target of KLF5.

We found that upregulation of myocardial Klf5 expression after LI-TAC preceded the induction of Igf1 (Figure 6C). Levels of both Klf5 and Igf1 expression were reduced in Klf5fl/fl;Pstn-Cre mice, as compared with those in Klf5fl/fl mice, during the 2-week observation period following the LI-TAC operation. The Igf1 promoter contains a KLF-binding motif (CCCCACCCAC) at −53 bp, which, in the rat, is reportedly important for promoter activity and bound by an as-yet-unidentified transcription factor (Figure 6D) (33). Reporter analysis of the Igf1 promoter showed that KLF5 transactivated this promoter, but KLF15, which is expressed in cardiac fibroblasts, as compared with cardio-myocytes and cardiac fibroblasts (34, 35), failed to do so, and mutation within the potential KLF5-binding motif abolished KLF5-dependent transactivation (Figure 6D). ChIP assays confirmed that KLF5 bound to the Igf1 promoter (Figure 6E). As reported (30–32), IGF-1 induced hypertrophy in cultured cardiomyocytes (Supplemental Figure 14A), and inhibition of IGFR-1 using a neutralizing antibody significantly suppressed cardiomyocyte hypertrophy induced by the fibroblast-conditioned medium (Figure 6F). Taken together, the results so far demonstrate that KLF5 directly regulates expression of Igf1, which appears to be a major cardiotoxic factor secreted by fibroblasts.

**Figure 3**

Fibroblast-specific deletion of Klf5 in Klf5fl/fl;Pstn-Cre mice. (A) Fibroblast-specific deletion of the floxed region in Pstn-Cre mice was examined using R26RstoplacZ indicator mice. LacZ expression was visualized using X-gal. Scale bars: 100 μm. (B) CD3+ cells within non-myocyte-enriched cell populations isolated from adult hearts were analyzed for surface expression of the fibroblast marker Thy1 and the endothelial marker CD31. (C) Relative expression levels of cell-lineage markers in adult cardiomyocytes (CM) isolated using the Langendorff perfusion method, and in Thy1+CD31−CD3− (Thy1+), and Thy1+CD31−CD3− (CD31+) cells sorted from non-myocyte-enriched populations as shown in B. Myh6 (encoding α-MHC), Ddr2 (encoding discoidin domain receptor 2), and Cd3e (encoding VE-cadherin) were used as markers for cardiomyocytes, fibroblasts, and ECs, respectively. The cells were isolated from 8-week-old mice subjected to sham operations. (D) Competitive PCR analysis for quantitation of Cre-mediated recombination of the Klf5 gene region in adult cardiomyocytes, CD31+ ECs, and Thy1− fibroblasts isolated from Klf5fl/fl and Klf5fl/fl;Pstn-Cre mice 2 weeks after either the sham or LI-TAC operation. Competitive PCR was performed as shown in Supplemental Figure 6B. (E) Relative expression levels of Klf5 mRNA in adult cardiomyocytes, Thy1+ fibroblasts, and CD31+ ECs isolated from Klf5fl/fl and Klf5fl/fl;Pstn-Cre mice as shown in B 5 days after either sham operation or LI-TAC. Expression levels of Klf5 mRNA were assessed using real-time PCR and normalized to those of 18s rRNA, after which they were further normalized to the levels in Thy1+ cells isolated from Klf5fl/fl mice subjected to the sham operation. *P < 0.01 versus sham control of the same genotype in the same cell lineage group; **P < 0.01 versus Klf5fl/+ mice subjected to LI-TAC in the same cell lineage group.
We also found that the numbers of fibroblasts positive for BrdU incorporation following LI-TAC were significantly smaller in Klf5<sup>fl/fl</sup>;Postn-Cre hearts than Klf5<sup>fl/fl</sup> hearts (Supplemental Figure 11B), which suggests that KLF5 may also be involved in modulating fibroblast proliferation, either autonomously (36–38) or by regulating autocrine/paracrine factors. Consistent with the latter, we found that IGF-1 induces fibroblast proliferation (Supplemental Figure 14B).

We previously reported that KLF5 also controls Pdgfa, which encodes PDGF-A, in response to angiotensin II (14, 39). At the same concentrations, PDGF-A was less able to induce cardiomyocyte hypertrophy than IGF-1 (Supplemental Figure 14A), though PDGF-A and IGF-1 similarly induced fibroblast proliferation (Supplemental Figure 14B). PDGF-A induced greater migration of fibroblasts in Boyden chamber assays than IGF-1 (Supplemental Figure 14C), suggesting PDGF-A is primarily involved in mediating the migration and proliferation of fibroblasts. Thus, among the paracrine factors controlled by KLF5, it appears to be a change in IGF-1 activity that is primarily responsible for the reduced cardiac hypertrophy observed in LI-TAC Klf5<sup>fl/fl</sup>;Postn-Cre hearts.

Figure 4
Fibroblast-specific deletion of Klf5 attenuates cardiac hypertrophy and fibrosis after TAC. Klf5<sup>fl/fl</sup> and Klf5<sup>fl/fl</sup>;Postn-Cre mice were subjected to LI-TAC or sham operation. (A) Representative low-magnification views of H&E-stained heart sections 2 weeks after the operations. Scale bar: 1 mm. The bottom-left panel was composited from 2 photographs of the same section. (B) Representative elastic picrosirius red–stained sections and fibrotic areas. Scale bars: 100 μm. (C) Fibrotic areas. (D) Heart weight/body weight ratios 2 weeks after the operations. (E) Echocardiographic analysis 2 weeks after the operations. (F) Relative cross-sectional areas of cardiomyocytes. (G) Relative expression levels of Nppa and Myh7 mRNA. Expression levels of each gene were normalized to 18s ribosomal RNA levels and then further normalized with respect to those obtained with samples from Klf5<sup>fl/fl</sup> mice subjected to sham operation. *P < 0.01 versus sham control of the same genotype; †P < 0.01 versus Klf5<sup>fl/fl</sup> subjected to TAC. n = 7.
Cardiac fibroblasts are essential for adaptive responses to severe pressure overload. Next we assessed the importance of cardiac fibroblasts in the adaptive responses of the myocardium for maintenance of cardiac function. 

Discussion

The results of the present study clearly demonstrate that cardiac fibroblasts play essential roles in cardioprotection and cardiomyocyte hypertrophy, at least in part by producing paracrine factors, including IGF-1. Based on the observation that in addition to extracellular matrix proteins, cardiac fibroblasts produce a variety of paracrine factors — some of which can induce hypertrophic responses in vitro — it has been postulated that an interplay between cardiomyocytes and fibroblasts is involved in cardiac hypertrophy and pathology (2, 3). However, the potential requirement for fibroblasts in the cardiac response to pathological stress in vivo has not been fully appreciated. Our study provides clear evidence that cardiac fibroblasts functionally contribute to the adaptive response to pressure overload in vivo. Particularly noteworthy is our finding that cardiac fibroblasts are absolutely required for protection of cardiac function in severe pressure overload. This means that cardiac fibroblasts are not mere bystanders acting only in fibrosis, but are crucial mediators of myocardial hypertrophy and adaptive responses in the heart. It was recently suggested that inappropriate angiogenesis plays an important role in heart failure (41). That finding, together with those summarized here, highlights the importance of the activities of the non-muscle cells residing in the myocardial interstitium. In addition to contributing to pathological remodeling, it is likely that these cells mediate homeostatic responses to physiological stress.

Our findings also indicate that KLF5 expressed in cardiac fibroblasts is a key regulator controlling the stress response in the myocardium. Moreover, the results obtained with cardiac fibroblast–specific Klf5-knockout mice suggest that IGF-1 produced by fibroblasts is also important for protective responses. These findings are consistent with the results of earlier studies of the effects...
of transgenic overexpression of IGF-1 and IGF-1 receptor in cardiomyocytes, which were also suggestive of IGF-1’s role in physiological hypertrophy and cardiac protection (42–46). Thus IGF-1 produced locally by fibroblasts appears to be a key mediator of cardiac hypertrophy and myocardial protection against pressure overload.

The present study identified IGF1 as the target of KLF5 in fibroblasts involved in the cardiac adaptive response. However, KLF5 also likely controls the expression of genes other than IGF1 and Pdgfa, including those encoding paracrine factors involved in regulating fibroblast function (Supplemental Table 1). We would therefore expect future studies of the gene networks controlled by KLF5 to shed additional light on their homeostatic and pathological functions. In that regard, it will also be important to analyze the possible interplay between KLF5 and other members of the KLF family. Previous studies have demonstrated the functional roles played by several KLFs in the heart (34, 35, 47, 48). For instance, KLF15 negatively regulates cardiac fibrosis (34). It is therefore conceivable that networks of KLFs contribute to the myocardial responses to stress. Finally, our results suggest that therapeutic modulation of cardiac fibroblast function may represent a novel approach to the prevention and/or treatment of heart failure.

Methods

For experimental procedures not described herein, see Supplemental Methods.

Animals. Mice were housed in temperature-controlled rooms with a 12-hour light/12-hour dark cycle. All experiments were approved by the University of Tokyo Ethics Committee for Animal Experiments and strictly adhered to the guidelines for animal experiments of the University of Tokyo.

Generation of Klf5-floxed mice. A 12-kb Klf5 fragment containing exons 1–3 was used to construct the targeting vector. The scheme for construction of the targeting vectors is shown in Supplemental Figure 5. The targeting construct was introduced into ES cells by electroporation, and G418-resistant clones were then examined for homologous recombination using Southern blot analysis with appropriate 3′ probes. Six ES clones that contained the correctly targeted Klf5 locus were obtained, and 2 were injected into 129/Sv blastocysts to obtain chimeric mice. Male chimeras were bred with female mice expressing the enhanced site-specific recombinase FLP to remove the FRT-flanked neomycin cassette to generate heterozygous Klf5-fl/fl mice. Expression levels were normalized to those of 18s rRNA and then further normalized with respect to those in cardiomyocytes. A P < 0.01 versus cardiomyocytes.

Figure 6

KLF5 transactivates the Igf1 promoter. (A) KLF5 knockdown reduced Igf1 expression in cardiac fibroblasts. KLF5 was knocked down as shown in Figure 5A. *P < 0.01 versus siCtrl. (B) Fibroblast-selective expression of Igf1. Igf1 mRNA levels in cultured cardiac fibroblasts were normalized to those of 18s rRNA and then further normalized with respect to those in cardiomyocytes. *P < 0.01 versus cardiomyocytes. (C) Cardiac expression of Klf5 and Igf1 mRNA after Li-TAC in Klf5fl/+ and Klf5fl/fl;Postn-Cre mice. Expression levels were normalized to those of 18s rRNA and then further normalized with respect to those in the hearts before TAC. (D) Reporter analysis of KLF5-dependent transactivation of the Igf1 promoter. Luciferase reporter constructs driven by the wild-type Igf1 promoter or a mutant promoter in which the potential KLF-binding site was mutated were cotransfected with either empty vector or a vector harboring Klf5 or Klf15. Data are representative of 3 independent experiments. (E) ChIP assays of KLF5 binding to the Igf1 promoter. An intronic region of Igf1 that does not contain a KLF-binding motif served as a negative control. (F) Effects of neutralizing IGF-1 on the cardiotoxic activity of fibroblast-conditioned medium. An antibody against IGF-1 (30 μg/ml) or normal IgG was added to the conditioned medium, after which the effect of the medium on cardiomyocyte surface area was analyzed. *P < 0.01 versus cells treated with SFM; #P < 0.01 versus cells treated with fibroblast-conditioned medium.
probe for hybridization (Supplemental Figure 5). The probe for intron 1 was made by PCR using primers 5′-TGTCGTGGTGCTTTGAGAAG-3′ and 5′-TATCTTCCAGGCCCTGATTG-3′. PCR for genotyping was performed with primers A (5′-GCATCAGGAGGGTTTCATGT-3′) and B (5′-GTCTCGGCCTCATGTAAG-3′), which yielded 164-bp and 331-bp products for wild-type and floxed Klf5 alleles, respectively.

Quantification of Cre-mediated recombination. Competitive PCR was performed to calculate the relative deletion frequency using primers A, B, and C (5′-TGACCCATTACCGAATCTACTG-3′), which produced 331-bp and 250-bp bands for the floxed and floxed-out Klf5 alleles, respectively. The respective abundances of the floxed and floxed-out Klf5 alleles were analyzed using real-time PCR with the same primer sets. To calculate absolute numbers of alleles in a given cell sample, we used external standards containing known numbers of DNA fragments derived from Klf5-floxed and floxed-out alleles.

TAC model. TAC was performed as described previously (50). Briefly, mice (8–10 weeks old, 21–24 g body weight) were anesthetized by intraperitoneal injection of a mixture of xylazine (5 mg/kg) and ketamine (100 mg/kg).

Figure 7
Cardiac fibroblasts are essential for the protective response elicited by severe pressure overload. (A–H) Klf5fl/fl and Klf5fl/fl;Postn-Cre mice were subjected to HI-TAC or sham operation. (A) Kaplan-Meier survival analysis of Klf5fl/fl (n = 16) and Klf5fl/fl;Postn-Cre (n = 10) mice after HI-TAC. *P < 0.05 versus Klf5fl/fl. (B) Representative pictures of lungs 2 weeks after the operations. Note the severe lung edema in Klf5fl/fl;Postn-Cre mice subjected to HI-TAC. (C) Lung weights in Klf5fl/fl (n = 5) and Klf5fl/fl;Postn-Cre (n = 3) mice 2 weeks after the operations. (D) Representative low-magnification views of H&E-stained heart sections 2 weeks after the operations. Scale bar: 1 mm. (E–G) Heart weight/body weight ratios (E), relative cross-sectional areas of cardiomyocytes (F), and fibrotic areas (G) in Klf5fl/fl (n = 5) and Klf5fl/fl;Postn-Cre (n = 3) mice 2 weeks after the HI-TAC operation. *P < 0.01 versus sham control of the same genotype; †P < 0.05 versus Klf5fl/fl mice subjected to HI-TAC. (H) M-mode echocardiographic tracings obtained 2 weeks after the operations.
The animals were then placed in a supine position, an endotracheal tube was inserted, and the animals were ventilated using a volume-cycled rodent ventilator with a tidal volume of 0.4 ml room air and a respiratory rate of 110 breaths/minute. The chest cavity was exposed by cutting open the proximal portion of the sternum. After the aortic arch between the innominate and left common carotid arteries was isolated, it was constricted with a 7-0 nylon suture tied firmly 3 times against a 25- or 27-gauge blunted needle for LI- and HI-TAC, respectively. Sham-operated mice underwent the identical surgical procedure, including isolation of the aorta, but without placement of the suture.

Administration of JB1, a peptide IGF-1 receptor antagonist. C57BL/6 mice (8–10 weeks old, 21–24 g body weight) were anesthetized by intraperitoneal injection of pentobarbital sodium (50 mg/kg). An incision was made in the midscapular region under sterile conditions, and an osmotic minipump (Alzet) containing either JB1 (BACHEM) dissolved in 0.15 mol/l NaCl and 1 mmol/l acetic acid or vehicle only was implanted. The delivery rate was 1 mg/kg/d for 14 days.

Echocardiography. Animals were lightly anesthetized with 2,2,2-tribromoethanol (200 mg/kg) and set in a supine position. Two dimensional (2D) guided M-mode echocardiography was performed using an echocardiogram (model 4500, Sonos) equipped with a 15 to 6 L MHz transducer (Philips). The heart at the level of the LV papillary muscle was imaged in the 2D mode in the parasternal short-axis view with a depth setting of 2 cm. LV diastolic posterior wall thickness (PWT), LV diastolic dimensions (LVDd), and LV end-systolic dimensions (LVDs) were measured. LV fractional shortening (%FS) was calculated as $(LVDd - LVDs)/LVDd \times 100$.

Histological analysis. Heart sections were prepared as described previously (14) and stained with H&E for overall morphology. Immunohistochemical staining of KLF5 was performed using an anti-KLF5 monoclonal antibody (KM1784). A biotin-conjugated goat anti-rat antibody, streptavidin-conjugated horseradish peroxidase (Dako), and 3,3′-diaminobenzidine (DAB) were used to visualize labeling. For double staining of KLF5 and αMHC, we also used anti-αMHC monoclonal antibody CMA19 (51). Simple Stain AP (Nichirei) and an Alkaline Phosphatase Substrate Kit I (Vector) were used to visualize labeling. To quantify cardiac interstitial fibrosis, we stained sections with elastic picrosirius red, after which images were captured with a digital camera and analyzed using Photoshop (Adobe) and Scion Image.

β-Galactosidase staining. Heart tissues were fixed for 12 hours at 4°C in PBS containing 0.4% glutaraldehyde, 0.01% Na deoxycholate, 0.1% NP40, 0.1 M MgCl₂, and 5 mM EGTA; rinsed 3 times for 30 minutes in PBS; and
then incubated for 24 hours at 37°C in a staining solution [1 mM MgCl₂, 20 mM K₂Fe(CN)₆, 20 mM K₂Fe(CN)₃, 1 mg/ml X-gal in PBS]. LacZ-stained sections were counterstained with nuclear fast red for nuclei, biotin-conjugated isocitron B4 (Vector) for ECs, and elastic picrosirus red for fibrosis. 

Cardiomyocyte cross-sectional area. Heart sections were deparaffinized, rehydrated, and incubated for 1 hour at room temperature with FITC-labeled wheat germ agglutinin (Sigma-Aldrich) to visualize myocyte membranes. Regions that included the circular shapes of capillaries were selected from the epicardial side of the LV free walls. The mean cross-sectional area of cardiomyocytes was determined for each mouse from 60 to 80 cells.

RNA extraction and real-time PCR. Heart tissues were stored in RNAlater RNA stabilization reagent (QIAGEN) at 4°C. Total RNA was extracted using an RNaseasy Fibrous Tissue Mini Kit (QIAGEN). First-strand cDNA synthesis was performed with 1 μg of total RNA, random hexamers, and SuperScript III Reverse Transcriptase (Invitrogen). Real-time PCR was performed using a QuantiTect SYBR Green PCR kit (QIAGEN) in a LightCycler (Roche). The expression level of each gene was normalized to that of 18s rRNA, which served as an endogenous internal control. The sequences of the PCR primers are shown in Supplemental Table 2. 

Isolation of neonatal and adult cardiomyocytes and non-myoctes. Neonatal ventricles from 1-day-old ICR mice were separated and minced in ice-cold balanced salt solution, as described previously with minor modifications (52). To isolate cardiac cells, the tissues were incubated in a balanced salt solution containing 0.2% collagenase type 2 ( Worthington Biochemical) for 6 minutes at 37°C with agitation. The digestion buffer was replaced 7 times, at which point the tissues were completely digested. The dispersed cells were incubated in 10-cm culture dishes for 80 minutes to remove non-myocytes. The unattached viable cells, which were rich in cardiomyocytes, were cultured on gelatin-coated dishes at 37°C in DMEM supplemented with 10% FBS and 10 μM cytosine 1-β-D-arabinofuranoside ( Ara C) to inhibit fibroblast proliferation. Using this protocol, we consistently obtained cell populations containing at least 90%-95% cardiomyocytes. Non-myocytes that attached to the dishes were cultured in DMEM supplemented with 10% FBS and allowed to grow to confluence, then they were trypsinized and passaged at 1:3. This procedure yielded cell cultures that were almost exclusively fibroblasts by the first passage. Experiments were carried out after 2 or 3 passages. 

Adult cardiomyocytes were isolated using the Langendorff perfusion method as previously described (27). For isolation of non-myocyte-enriched cells, hearts were dissected free of vessels and atria, washed in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich), and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces. The heart pieces were incubated in ice-cold modified Krebs-Henseleit bicarbonate (KHB) buffer (pH 7.2) (Sigma-Aldrich) and quickly cut into pieces.

Flow cytometric analysis and sorting. Single cells were isolated from adult hearts and incubated with PE-conjugated anti-Thy1 antibody (eBioscience), FITC-conjugated anti-CD31 antibody (BD Biosciences), and allophycocyanin-conjugated CD34 antibody (eBioscience), after which they were analyzed and sorted using a FACSAria II (BD Biosciences) and FlowJo software. For analysis of β-galactosidase expression and the sorting of LacZ⁺ cells, a FluorReporter LacZ Flow Cytometry Kit ( Molecular Probes, Invitrogen) was used according to the manufacturer’s recommendations. Cells were stained with the fluorogenic β-galactosidase substrate fluorescein di-β-D-galactopyranoside (FDG).

Production of medium conditioned by cardiac fibroblasts. Cardiac fibroblasts were grown to subconflueny in 10-cm dishes. The medium was then replaced with fresh serum-free DMEM, and the cells were incubated for additional 48 hours. The medium was then collected as conditioned medium.

siRNA. siRNA for Klf5 and control siRNA were purchased from Dharmacon. Using Lipofectamine RNAiMax (Invitrogen), the siRNA at a final concentration of 20 nM in 10 ml of culture medium was transfected into mouse cardiac fibroblasts plated in 10-cm culture dishes. siRNA-mediated knockdown of Klf5 did not affect mRNA expression levels in KLF family members that reportedly function in the cardiovascular system (e.g., Klf2, Klf4, Klf10, Klf13, and Klf15) (Supplemental Figure 16).

Morphometric studies of cells. Neonatal cardiomyocytes cultured in 3.5-cm dishes were maintained in serum-free DMEM for 24 hours, after which the culture medium was replaced with either fresh serum-free DMEM or medium conditioned by cardiac fibroblasts. To analyze the effects of neutralizing IGF-1, either anti-IGF-1 neutralizing antibody (Millipore) or control IgG (Sigma-Aldrich) was then added, and the cells were cultured for an additional 24 hours. To analyze the effects of growth factors, cells were first cultured for 24 hours in serum-free DMEM. The medium was then replaced with serum-free DMEM containing vehicle, IGF-1 (Wako), or PDGF-A (R&D Systems), and the cells were cultured for an additional 24 hours. The cells were then fixed in 2% paraformaldehyde and permeabilized for 10 minutes with 0.5% Triton X-100 (Sigma-Aldrich) in PBS, after which they were incubated in PBS containing 1% bovine serum albumin for 10 minutes to block non-specific staining. They were then incubated with anti-sarcomeric α-actinin antibody (Sigma-Aldrich), followed by treatment with an Alexa-conjugated secondary antibody. Cardiomyocyte size was determined by measuring the surface area of sarcomeric α-actinin-positive cells. 

Enzyme-linked immunon assay. To analyze secretion of ANP, cardiomyocytes were cultured in the serum-free DMEM for 24 hours and then stimulated with fresh serum-DMEM or medium conditioned by cardiac fibroblasts for 48 hours. The concentration of ANP protein in the culture medium was measured using an enzyme-linked immunonassay kit (Phoenix Pharmaceuticals).

Analysis of expression of alternatively spliced Igf1 mRNA. Igf1-GF is controlled by 2 distinct promoters associated with untranslated exons 1 and 2, which generate two types of mRNA, containing either exon 1 (class 1 mRNA) or exon 2 (class 2 mRNA) plus a common block of translated exons (53–55). Expression of the two transcripts is differentially regulated in different tissues and species and during development. We therefore determined which mRNA was the major transcript in mouse heart. The respective abundances of the two transcripts were analyzed using real-time PCR with primer sets that specifically amplified either the class 1 or class 2 mRNA. To calculate absolute numbers of transcripts in a given amount of total RNA, we used external standards containing known numbers of class 1 or 2 cDNA fragments. We found that class 2 transcripts were much more abundant in both cardiac fibroblasts and cardiomyocytes than class 1 transcripts, and also in hearts after LI-TAC (Supplemental Figure 17). We therefore analyzed expression of class 2 mRNA as the major Igf1 transcript in the heart and cardiac fibroblasts (Figure 6, A–C). Igf1 class 1 and class 2 cDNA fragments were amplified using a forward primer specific for each leader exon (exon 1, 5′-ATGGGAAAATACGACGTTC-3′; exon 2, 5′-CTGCCGCT-GTAAACGACCGCGG-3′) and a reverse primer (exon 3-4 junction, 5′-GGCTT-GCTTTTGTAGGCTTCAGTGG-3′). 

Igf1 promoter–luciferase constructs. Because the class 2 Igf1 mRNA is much more abundantly expressed than class 1 mRNA in the heart, we analyzed...
the promoter associated with exon 2 (33). A genomic fragment of the 5′-flanking region and a part of exon 2 (-80 to +43 bp) was obtained by PCR using mouse genomic DNA. The PCR fragment was then subcloned into a pG3L basic luciferase reporter vector (Promega) to generate pG3L-Igf1. A mutation within the potential KLF-binding motif was introduced by PCR to generate pG3L-igf1mtKLF. NIH-3T3 cells grown to 60%–80% confluence were then transfected with the vectors, after which luciferase activities were measured and normalized to β-galactosidase activity. The KLFs expression vector was described previously (57). The KLFs expression vector was obtained by inserting the KLFs cDNA into pCAGMS (14).

ChIP. ChIP assays were performed as previously described (29, 58). Mouse cardiac fibroblasts were formalin fixed, and then chromatin samples were immunoprecipitated using anti-KLF5 mouse monoclonal antibody (KM3918) or control IgG antibody. PCR was performed with the following region-specific primers: for the mouse IGF1 KLF5 site within the exon 2-associated promoter, 5′-ACCCAGGCTCAGACCATC-3′ and 5′-GGGTCGTATACAGCAGGT-3′; for intron 2 (an intronic region +750 bp from the translation initiation site that does not contain KLF-binding motifs; negative control), 5′-CCTCAGGCGCTTCAGAAGA-3′ and 5′-CATCAGGCGCTTCATGGTCT-3′; and for the pGL3 KLF5 site, 5′-ATG-TCGCTGCTGCAGTACG-3′ and 5′-CGACAGGGAGGGGTTATAG-3′.

Statistics. Data are shown as mean ± SEM. Paired data were evaluated using Student’s t test. Comparisons between multiple groups were made using 1-way ANOVA followed by a post-hoc Bonferroni test. Survival rates among mice were analyzed using long-rank test. P values less than 0.05 were considered statistically significant.

Acknowledgments

We thank Y. Namanaka, Y. Xiao, A. Ono, M. Hayashi, and E. Magoschi for their excellent technical assistance. This study was supported by Grants-in-Aid for Scientific Research (to N. Takeda, I. Manabe, R. Nagai) and a grant for Translational Systems Biology and Medicine Initiative from the Ministry of Education, Culture, Sports, Science and Technology of Japan; a research grant from the National Institute of Biomedical Innovation (to R. Nagai); and a research grant from the Japan Science and Technology Institute (to I. Manabe). P. Snider is supported by NIH T32 HL079995 Training Grant in Vascular Biology and Medicine, and S.J. Conway is partially supported by the Riley Children’s Foundation and the NIH.
