Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most prevalent arthropod-borne illness in the United States and remains a clinical and social challenge. The spectrum of disease severity among infected patients suggests that host genetics contribute to pathogenic outcomes, particularly in patients who develop arthritis. Using a forward genetics approach, we identified the lysosomal enzyme β-glucuronidase (GUSB), a member of a large family of coregulated lysosomal enzymes, as a key regulator of Lyme-associated arthritis severity. Severely arthritic C3H mice possessed a naturally occurring hypomorphic allele, *Gusβ*. *C57BL/6* mice congenic for the C3H *Gusb* allele were prone to increased Lyme-associated arthritis severity. Radiation chimera experiments revealed that resident joint cells drive arthritis susceptibility. C3H mice expressing WT *Gusβ* as a transgene were protected from severe Lyme arthritis. Importantly, the *Gusβ* allele also exacerbated disease in a serum transfer model of rheumatoid arthritis. A known GUSB function is the prevention of lysosomal accumulation of glycosaminoglycans (GAGs). Development of Lyme and rheumatoid arthritis in *Gusβ*-expressing mice was associated with heightened accumulation of GAGs in joint tissue. We propose that GUSB modulates arthritis pathogenesis by preventing accumulation of proinflammatory GAGs within inflamed joint tissue, a trait that may be shared by other lysosomal exoglycosidases.

**Introduction**

Lyme disease, caused by the spirochete *Borrelia burgdorferi* (1), is the most prevalent arthropod-borne illness in the United States. More than 30,000 cases are reported each year, while estimates suggest that around 300,000 are diagnosed annually (2, 3). Disease severity varies greatly among the affected population, with up to 60% of untreated patients developing a self-limiting, inflammatory arthritis. More than 30,000 cases are reported each year, while estimates the most prevalent arthropod-borne illness in the United States. The spectrum of disease severity among infected patients suggests that host genetics contribute to pathogenic outcomes, particularly in patients who develop arthritis. Using a forward genetics approach, we identified the lysosomal enzyme β-glucuronidase (GUSB), a member of a large family of coregulated lysosomal enzymes, as a key regulator of Lyme-associated arthritis severity. Severely arthritic C3H mice possessed a naturally occurring hypomorphic allele, *Gusβ*. *C57BL/6* mice congenic for the C3H *Gusb* allele were prone to increased Lyme-associated arthritis severity. Radiation chimera experiments revealed that resident joint cells drive arthritis susceptibility. C3H mice expressing WT *Gusβ* as a transgene were protected from severe Lyme arthritis. Importantly, the *Gusβ* allele also exacerbated disease in a serum transfer model of rheumatoid arthritis. A known GUSB function is the prevention of lysosomal accumulation of glycosaminoglycans (GAGs). Development of Lyme and rheumatoid arthritis in *Gusβ*-expressing mice was associated with heightened accumulation of GAGs in joint tissue. We propose that GUSB modulates arthritis pathogenesis by preventing accumulation of proinflammatory GAGs within inflamed joint tissue, a trait that may be shared by other lysosomal exoglycosidases.
Figure 1
Positional mapping and characterization of the Gusb<sup>+</sup> allele. (A) Advanced congenic lines identify regulatory subintervals within Bbaa2. Each row represents the genetic makeup of 1 congeneric mouse line across the Bbaa2 interval (120.3 to 141.2 Mb) on mouse chromosome 5. White and black portions of each row represent areas inherited from the B6 or C3H background, respectively. Ankle swelling measurements taken 4 weeks after B. burgdorferi infection (n = 12 to 35 mice per group; overall P < 0.0001). Significance of cosegregation (right) between ankle swelling and blinded scores of joint histopathology and PMN infiltration, assessed by 1-tailed Mann-Whitney test. (B) Inheritance of the Gusb polymorphism among strains included in the Sanger SNP resequencing database. (C) C3H mice and congenics carrying the Gusb<sup>+</sup> allele exhibited enzymatic hypomorphism in serum and bone marrow–derived macrophage cell extracts and supernatants (n = 4). (D) CBA/Ca expressed near normal serum GUSB activity, while CBA/J shared the C3H GUSB hypomorphism. (E) CBA/J developed severe Lyme arthritis, while CBA/Ca were resistant (n = 5 [B6 and C3H] and 10 [CBA substrains] mice in each group; overall P < 0.0001). Significance assessed by 1-way ANOVA followed by Dunnet’s multiple comparison test versus B6 (A and E) or Bonferroni’s post test (C and D). *P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001.
In this study, we report the positional cloning of a key genetic regulator underlying the increased Lyme arthritis severity conferred by \( Bbaa2 \) in C3H mice, the lysosomal enzyme \( \beta \)-glucuronidase, \( Gusb \). The hypomorphic C3H allele, \( Gusb^h \), was found to cause increased arthritis severity in mouse models of both Lyme and rheumatoid arthritis. \( Gusb \) belongs to a recently recognized group of lysosomal enzymes that modulate lysosomal storage and function and that are coregulated in response to stress. We propose that mild deficiencies in \( Gusb \) and other coregulated lysosomal enzymes may have previously unrecognized impact on a variety of inflammatory pathologies.

**Results**

**Positional cloning of \( Gusb \).** Through additional backcrossing to the parental B6 line, we developed 15 advanced B6.C3H-\( Bbaa2 \) congenic mouse lines harboring subintervals of \( Bbaa2 \) C3H from 120.3 to 141.2 Mbp (Figure 1A and ref. 21). After infection with \( B. burgdorferi \), the various subinterval congenic lines exhibited a wide spectrum of disease severity, as assessed quantitatively by ankle swelling measurements. Compared with B6, congenic mice harboring C3H-derived intervals from 129.0–130.5 Mbp (\( P < 0.01 \)), 133.5–141.2 Mbp (\( P < 0.05 \)), and 125.3–128.2 Mbp (\( P < 0.05 \)) within \( Bbaa2 \) exhibited significantly more severe disease. The ankle swelling data also support the presence of a negative regulatory element within \( Bbaa2 \) (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI72339DS1). Moreover, for the 129.0–130.5 Mbp and 133.5–141.2 Mbp intervals, increases in the categorical traits of pathology score and neutrophil (PMN) infiltration cosegregated with ankle swelling. Consequently, they have been designated \( Bbaa2a \) and \( Bbaa2b \), respectively.

\( Bbaa2a \) sequence analysis revealed a high degree of conservation between B6 and C3H mice, exhibiting very low SNP density (21). This interval contains 24 genes (Supplemental Figure 2), none of which are differentially expressed at the transcriptional level between B6 and C3H mice following infection, as measured by microarray analysis (20). The Sanger SNP resequencing database (22) indicates that the interval harbors only 1 high-confidence coding nonsynonymous G→A polymorphism differing between B6 and C3H strains, which causes a T87I amino acid change in the ubiquitously expressed lysosomal enzyme \( Gusb \) (Figure 1B).
GUSB hypomorphism influences arthritis severity through a cell-intrinsic mechanism. Radiation chimeras were generated between B6 and B6.C3H-Bbaa2 in all pairwise combinations. We achieved high level (>90%) engraftment of B cells and myeloid lineages (Supplemental Figure 6). (A) Chimera serum GUSB activity levels were determined by the donor cell source. (B and C) The C3H Bbaa2 locus contributed to more severe Lyme arthritis, primarily through the activity of radiation resistant joint resident cells. Notably, the B6→Bbaa2 group developed severe Lyme arthritis despite high serum GUSB levels, and the Bbaa2→B6 group was resistant despite low serum GUSB levels (n = 16 to 20 rear ankle joints, 8 to 10 mice per group; overall P < 0.0001). Significance of ankle swelling assessed by 1-way ANOVA followed by Dunnet’s multiple comparison test versus the B6→B6 transplant control. Significance of overall lesion scores assessed by Mann-Whitney test versus the B6→B6 transplant control, with Bonferroni correction. *P < 0.05; **P < 0.01; ***P < 0.0001.

Loss of GUSB function exacerbates Lyme arthritis severity in a genetically recessive manner. The availability of a spontaneous Gusb mutant mouse line on the resistant B6 genetic background, B6.C3H-GusbNull, allowed us to determine the impact of GUSB loss of function in a second, independent mouse line. This GusbNull strain is also a congenic line (Methods), and GusbNull homozygotes are used as a mouse model of mucopolysaccharidosis type VII (MPSVII). Importantly, we determined that GusbNull mice exhibit no defect in host defense (Figure 2A) despite expressing only 1% of normal GUSB levels in homozygotes (Figure 2B). Infected homozygous GusbNull mice developed maximally severe Lyme arthritis, while heterozygous littermates carrying 1 functional Gusb allele were protected (Figure 2C). We corroborated the finding that heterozygous animals were protected with both our full-length B6.C3H-Bbaa2 and our B6.C3H-GusbNull congenic mouse lines (Figure 2, D and E). Thus, neither the severe GusbNull allele nor the hypomorphic Gusb allele act in a dominant negative fashion to interfere with the protective activity of functional Gusb alleles present in these heterozygous animals.

GUSB hypomorphism acts through a cell-intrinsic mechanism. GUSB functions as a lysosomal hydrolase that requires the low pH of the lysosome for full enzymatic activity, but is also present in cell-free supernatants obtained from strain-specific bone marrow–derived macrophages (Figure 1C). We observed no significant differences in Gusb mRNA levels between strains or following B. burgdorferi infection, indicating that this hypomorphism manifests posttranscriptionally (Supplemental Figure 3). The Sanger SNP database indicates that only 3 of the 18 included strains, C3H/HeJ, AKR/J, and CBA/J, share this Gusb coding variant. Both C3H and AKR/J have previously been shown to develop severe Lyme arthritis (13, 25). Intriguingly, the lower density CDG-MDA1 database shows that unlike CBA/J, a closely related CBA/Ca strain carries the common B6 reference nucleotide, which we verified by PCR SNP genotyping (Supplemental Figure 4 and ref. 26). These CBA substrains arose from a partially inbred line and have been genetically isolated but never outcrossed (27), suggesting the Gusb allelic difference is likely to be the result of a limited amount of residual heterozygosity that existed prior to separation. Consistent with this genetic difference, analysis of serum GUSB enzymatic activity levels confirmed that, although CBA/Ca mice had levels similar to those of B6, CBA/J mice were GUSB hypomorphs like C3H mice (Figure 1D). Following B. burgdorferi infection, CBA/J mice developed severe arthritis, while CBA/Ca were resistant (Figure 1E). Importantly, the middensity CDG-MDA1 database identifies only 118 coding nonsynonymous SNPs in the entire genome distinguishing between CBA/Ca and CBA/J mice, and only this Gusb polymorphism was positioned within any of the previously identified Bbaa QTL (17, 19, 28), including the Bbaa2 region referenced in Figure 1A.

C3H mice carry a natural variant of Gusb that is functionally hypomorphic. The C3H strain is known to carry a functionally hypomorphic Gusb allele, which confers a 70%–90% reduction in enzymatic activity in the serum and various tissues (23, 24). We verified that our B6.C3H-Bbaa2 congenic mice exhibited hypomorphic GUSB enzymatic activity in serum and in cell extracts and supernatants obtained from strain-specific bone marrow–derived macrophages (Figure 1C). We observed no significant differences in Gusb mRNA levels between strains or following B. burgdorferi infection, indicating that this hypomorphism manifests posttranscriptionally (Supplemental Figure 3). The Sanger SNP database indicates that only 3 of the 18 included strains, C3H/HeJ, AKR/J, and CBA/J, share this Gusb coding variant. Both C3H and AKR/J have previously been shown to develop severe Lyme arthritis (13, 25). Intriguingly, the lower density CDG-MDA1 database shows that unlike CBA/J, a closely related CBA/Ca strain carries the common B6 reference nucleotide, which we verified by PCR SNP genotyping (Supplemental Figure 4 and ref. 26). These CBA substrains arose from a partially inbred line and have been genetically isolated but never outcrossed (27), suggesting the Gusb allelic difference is likely to be the result of a limited amount of residual heterozygosity that existed prior to separation. Consistent with this genetic difference, analysis of serum GUSB enzymatic activity levels confirmed that, although CBA/Ca mice had levels similar to those of B6, CBA/J mice were GUSB hypomorphs like C3H mice (Figure 1D). Following B. burgdorferi infection, CBA/J mice developed severe arthritis, while CBA/Ca were resistant (Figure 1E). Importantly, the middensity CDG-MDA1 database identifies only 118 coding nonsynonymous SNPs in the entire genome distinguishing between CBA/Ca and CBA/J mice, and only this Gusb polymorphism was positioned within any of the previously identified Bbaa QTL (17, 19, 28), including the Bbaa2 region referenced in Figure 1A.

Loss of GUSB function exacerbates Lyme arthritis severity in a genetically recessive manner. The availability of a spontaneous Gusb mutant mouse line on the resistant B6 genetic background, B6.C3H-Gusb<mps-2>/BraJ (GusbNull), allowed us to determine the impact of GUSB loss of function in a second, independent mouse line. This GusbNull strain is also a congenic line (Methods), and GusbNull homozygotes are used as a mouse model of mucopolysaccharidosis type VII (MPSVII). Importantly, we determined that GusbNull mice exhibit no defect in host defense (Figure 2A) despite expressing only 1% of normal GUSB levels in homozygotes (Figure 2B). Infected homozygous GusbNull mice developed maximally severe Lyme arthritis, while heterozygous littermates carrying 1 functional Gusb allele were protected (Figure 2C). We corroborated the finding that heterozygous animals were protected with both our full-length B6.C3H-Bbaa2 and our B6.C3H-GusbNull congenic mouse lines (Figure 2, D and E). Thus, neither the severe GusbNull allele nor the hypomorphic Gusb allele act in a dominant negative fashion to interfere with the protective activity of functional Gusb alleles present in these heterozygous animals.

GUSB hypomorphism acts through a cell-intrinsic mechanism. GUSB functions as a lysosomal hydrolase that requires the low pH of the lysosome for full enzymatic activity, but is also present in cell-free supernatants obtained from strain-specific bone marrow–derived macrophages (Figure 1C). We observed no significant differences in Gusb mRNA levels between strains or following B. burgdorferi infection, indicating that this hypomorphism manifests posttranscriptionally (Supplemental Figure 3). The Sanger SNP database indicates that only 3 of the 18 included strains, C3H/HeJ, AKR/J, and CBA/J, share this Gusb coding variant. Both C3H and AKR/J have previously been shown to develop severe Lyme arthritis (13, 25). Intriguingly, the lower density CDG-MDA1 database shows that unlike CBA/J, a closely related CBA/Ca strain carries the common B6 reference nucleotide, which we verified by PCR SNP genotyping (Supplemental Figure 4 and ref. 26). These CBA substrains arose from a partially inbred line and have been genetically isolated but never outcrossed (27), suggesting
Notably, the disease severity of the B6→B6.C3H-Bbaa2 group was increased despite high GUSB activity levels in the serum. Conversely, B6.C3H-Bbaa2→B6 chimeric mice did not develop significantly more severe disease than the B6→B6 control group, despite low serum GUSB activity. These results indicate that GUSB hypomorphism primarily modulates disease severity within joint-resident, radiation-resistant cells and that serum GUSB levels are not determinative. This suggests that GUSB hypomorphism acts through a localized, cell-intrinsic mechanism to initiate the development of inflammatory arthritis.

Transgenic overexpression of GUSB in C3H mice reduces Lyme arthritis severity. Because Gusb does not appear to interfere with the function of Gusb in a dominant negative fashion in our various heterozygous experiments and because our radiation chimera experiments implicate joint resident cell types in arthritis development, transgenic overexpression to correct GUSB levels in a hypomorphic strain was considered a reasonable approach. To determine the magnitude of the Gusb effect, a transgene driving ubiquitous mouse Gusb expression (Figure 4A) was used to produce C3H/HeN-CAG-Gusb transgenic mice (Gusb). Five founders were identified that met or exceeded the serum GUSB enzymatic activity levels in all tissues. Fol-}

Figure 4
Correction of GUSB hypomorphism in C3H mice is protective. (A) Transgenic overexpression of mouse Gusb by a pCAGGS-based mammalian expression construct (58). (B) Five founders exhibited elevated GUSB serum activity relative to a β-galactosidase internal control. (C) C3H Gusb mice developed markedly less severe Lyme arthritis than WT C3H controls (n = 10 for B6 and C3H control groups, n = 22 total Gusb progeny from 4 different founders, no. 38 was infertile; overall P < 0.001). Significance assessed by 1-way ANOVA and Bonferroni’s post test (ankle swelling) or nonparametric Kruskal-Wallis test and Dunn’s multiple comparison test (histopathology). ***P < 0.01; **P < 0.001.

exhibited a profound and highly significant (P < 0.001) reduction in disease severity (Figure 4C) relative to WT C3H control mice. This argues that among the many Bbaa loci previously identified to regulate Lyme arthritis severity in C3H mice, Gusb is a key regulator.

Evidence of a conserved role for Gusb in a model of rheumatoid arthritis. Because the B6.C3H-Gusb congenic line provides the greatest genetic stringency to interrogate the specific impact of GUSB hypomorphism on a resistant genetic background, we used it to determine whether alterations in Gusb modulate disease severity in a way that is unique to Lyme arthritis or whether it plays a more generalized role. To test this, we used the K/BsxN serum transfer model of rheumatoid arthritis as a second experimental approach to inducing disease (30, 31). This model isolates the downstream effector phase of disease pathogenesis from the initiation phase through adoptive transfer of arthritogenic autoantibodies to induce a joint-specific inflammatory arthritis. Injection of submaximal doses of K/BsxN serum was useful in determining the unique contribution of Gusb to arthritis severity in this model. Following intraperitoneal injections of 100 μL K/BsxN serum on days 0 and 2, we found that our B6.C3H-Gusb congenic mice began to exhibit more severe ankle swelling than B6 control animals beginning on day 4, which was further exacerbated on day 7 (Figure 5A). Histopathology scores for joints at day 7 also corroborated the significance (P < 0.05) of this effect (Figure 5B).

GUSB deficiency is associated with excessive accumulation of glycosaminoglycans during arthritis development. GUSB is a lysosomal hydrolase that catalyzes an essential step in the homeostatic degradation of glycosaminoglycans (GAGs). Severe autosomal recessive GUSB deficiency causes a lysosomal storage disease known as MPSVI, one characteristic of which is spontaneous accumulation of partially degraded GAGs within lysosomes (32). C3H mice begin to develop mild lysosomal accumulation of GAGs by 12 months of age, but younger 9- to 11-week-old mice appear to be unaffected (33). GAGs and partially degraded fragments have previously been implicated as direct mediators of inflammation through activation of TLRs (34). Rodent models of lysosomal storage disease have been shown to exhibit less severe symptoms following the genetic removal of TLR4 or the pharmacological blockade of TNF-α signaling, consistent with an inflammatory component to disease pathogenesis (35, 36). To determine whether GAG accumulation occurs during arthritis development in our GUSB-deficient strains, we performed Alcian blue staining to detect the presence of acidic polysaccharides, including GAGs, in joint histopathology sections at 4 weeks after infection. The inflamed tissues from Gusb and Gusb strains consistently stained intensely positive for the presence of GAGs. Alcian blue-positive material was identified in the periarthritis soft tissue, particularly the tendon sheath, of the joints of Gusb and Gusb strains (Figure 6, B, D, F, and H). GAG accumulation was associated with severe tendonitis manifested by acute inflammation composed of dense neutrophilic infiltrates, tendon hyperproliferation, and synovial hypertrophy. In contrast, no significant accumulation of Alcian blue-positive material or inflammation was detected in joints from C3H Gusb and other GUSB-sufficient strains (Figure 6, A, C, E, and G). Similarly, joints from day 7 K/BsxN-treated B6 control animals lacked GAG accumulation despite noting that Gusb progeny
moderate swelling (Figure 6I) in contrast to the severely swollen joints from B6.C3H-Gusbh congenic mice, which exhibited severe arthritis with extensive accumulation of GAGs throughout the periarticular tissue, including the posterior leg and footpad (Figure 6J). To quantify the approximate magnitude of this effect for each group, all joint sections stained for Alcian blue were scored for GAG accumulation (Figure 6K).

**Discussion**

We have uncovered a key role for a naturally occurring hypomorphic C3H Gusbh allele in Lyme arthritis severity using a scientifically rigorous QTL mapping approach. All tested inbred mouse strains that carry Gusbh are genetically susceptible to severe Lyme arthritis, and introgression of either Gusbh or the more severe Gusbhnull onto a resistant B6 genetic background confers susceptibility. Importantly, Gusbhnull homozygous animals develop a maximal Lyme arthritis response, equivalent to that of C3H-positive control animals, while strains with the milder hypomorphism conferred by Gusbh develop significant (P < 0.01) arthritis of intermediate severity. Additionally, correction of the Gusbh deficiency through transgenic overexpression of Gusbh confers significant (P < 0.001) protection to genetically susceptible C3H mice, conclusively and specifically demonstrating a key role for Gusbh.

It is well established that mutations causing frank deficiencies in GUSB result in spontaneous and overt lysosomal storage disease, although mild deficiencies may go unrecognized until late in life and are often misdiagnosed as an inflammatory joint disease (37). Human Gusbh is known to be polymorphic, with over 750 SNPs recorded in the dbSNP database. Forty-nine mutations causing overt disease have been identified in MPSVII patient populations (32), while the prevalence and impact, if any, of other variants remain undefined. Human GUSB enzymatic activity levels in the general population have been shown to exhibit a wide distribution and vary in tissue and serum samples by up to 30-fold (38, 39), differencedes larger than those observed between high-expressing (B6, CBA/Ca) and low-expressing (C3H, CBA/J) inbred mouse strains used in this study (Figure 1D and ref. 33). GUSB may be uniquely sensitive to mild deficiencies in enzymatic activity, since it has been suggested as the rate-limiting enzyme in the dermatan sulfate degradative pathway (40). Severe deficiencies in individual lysosomal enzymes causing overt disease are rare, with a combined incidence estimated at up to 1 in 5,000 births (41), far below the practical limit of detection of genome wide association studies (GWAS) (minor allele frequency > 0.05) (42). Although human genetic susceptibility to Lyme arthritis has not been investigated by GWAS, it is noteworthy that thus far only a fraction of the genetic variance underlying rheumatoid arthritis has been identified by GWAS (43), accentuating the added value of our QTL mapping approach.

Our studies have identified a naturally occurring, mild subclinical GUSB deficiency that transforms the normally protective local response to *B. burgdorferi* into a fulminating inflammatory arthritis. Recent literature has brought attention to the persistence of bacterial antigen in host tissues, even following antibiotic regimens that effectively cleared cultivable bacteria (44). Importantly, the increased disease severity we have observed occurs in the absence of significant alterations in host defense or *B. burgdorferi* load in tissues (Figure 2A). This disease exacerbation is also retained in the distinct and well-characterized K/BxN serum transfer model of rheumatoid arthritis, where dosage of the inflammatory stimulus can be tightly controlled. This suggests that inflammatory initiators such as *B. burgdorferi* antigen or autoantibodies trigger severe disease through a 2-hit phenomenon, where coincident breakdown of host tolerance mechanisms designed to limit the pathological consequences of infection and the ensuing inflammatory response instead exacerbate disease symptoms. The ability of Gusbh to exacerbate arthritis in response to very different experimental stimuli suggests this phenomenon may also be generalizable to other inflammatory triggers.

Our observation that radiation-resistant, joint-resident cells are a primary determinant of the magnitude of the Lyme arthritis response offers important insight into the mechanisms underlying joint pathogenesis in this model. This finding indicates that resident cells have important roles both in recruiting inflammatory immune cells to help clear infection and in mitigating damage through tolerance mechanisms. Our complementary finding that the severe joint pathology observed in infected B6.C3H-Bhax2 mice is not effectively corrected by high-serum GUSB levels bears striking resemblance to reports on the limited efficacy of enzyme replacement therapy to alleviate musculoskeletal symptoms in adult animal models of MPSVII (45, 46), although early intervention in neonates has shown promise (47, 48). Similarly, the joint pathologies in patients with a variety of mucopolysaccharidoses are difficult to treat and respond...
much more slowly to high-dose enzyme replacement therapy than other symptoms, such as hepatosplenomegaly or sleep apnea (49). Taken together, these findings highlight the importance of the primary response to bacterial stimulation that is mounted by resident cells in these refractory joint tissues.

The evident link between GUSB hypomorphism and excessive deposition of GAGs with potential proinflammatory activity provides a plausible mechanism bridging disease to the critical catalytic role GUSB plays in homeostatic GAG degradation. Although our data show no significant change in bacterial load due to GUSB deficiency, GAG-mediated cell adhesion by *B. burgdorferi* does play a noteworthy role in mammalian infection and tissue localization (50). The GUSB substrate dermatan sulfate has been linked to excessive TNF-α release by chondrocytes (40), and MPSVI symptoms are alleviated by blocking TNF-α (36), a highly successful target for rheumatoid arthritis (51). However, this does not preclude the involvement of other downstream effectors. The release and accumulation of lysosomal exoglycosidasates in the serum has been observed in multiple forms of chronic inflammatory arthritis, with localized release into synovial fluid reported to be especially exaggerated in chronic Lyme arthritis patients (52, 53). Although lysosomal exoglycosidasates such as GUSB are catalytically inactive at neutral pH, coincident release of other proinflammatory lysosomal components may provide an alternate mechanism to trigger or amplify a local inflammatory cascade (54). We suggest that the identification of *Gusb* as a key regulator of murine Lyme and rheumatoid arthritis severity provides a sound scientific basis for future investigations into serum GUSB or GAG levels as potential biomarkers of human susceptibility to developing chronic or severe inflammatory arthritis.

*Gusb* is 1 member of a large group of over 40 coregulated lysosomal enzymes in the coordinated lysosomal expression and regulation (CLEAR) network that are responsible for the stepwise degradation of several distinct biological substrates, including GAGs, lipids, sugars, chitin, and glycogen (55). As with *Gusb*, severe deficiencies in virtually all of these enzymes induce spontaneous lysosomal storage disease. Many such lysosomal storage diseases exhibit progressive joint disease. Recent work has demonstrated that overexpression of the master regulatory transcription factor of the CLEAR network, TFEB, leads to successful clearance of glycogen from lysosomes in both in vitro and mouse models of Pompe disease (56). Based on the close regulatory and functional interrelationship between *Gusb* and other lysosomal enzymes, we propose that the increased arthritis severity observed in this study may also be generalizable to mild deficiencies in other members of the CLEAR network.
Methods

Generation of interval-specific congenic lines

Interval-specific congenic lines (ISCL) were generated as described (19). Standard nomenclature for the mouse lines is used herein, as follows: the background strain (e.g., C57BL/6Ncr, abbreviated B6 in the ISCL designations) is listed first, followed by the donor strain (e.g., C3H) and the introgressed interval on mouse chromosome 5 (in Mbp, according to the NCBI37/mm9 Mouse Genome Assembly) from C3H/HeOuNT into the C57BL/6Ncr parental strain (National Cancer Institute). B6.C3H-120.3-141.2 (Full Length, B6.C3H-Bbaa2), B6.C3H-120.3-121.6, B6.C3H-120.3-125.6, B6.C3H-120.3-126.6, B6.C3H-120.3-128.2, B6.C3H-125.3-128.2, B6.C3H-120.3-131.0, B6.C3H-125.3-131.8, B6.C3H-129.0-130.5 (B6.C3H-Gusbb), B6.C3H-129.0-141.2, B6.C3H-131.8-133.5, B6.C3H-131.8-141.2, B6.C3H-134.7-141.2, and B6.C3H-136.4-141.2 ISCL were generated by marker-assisted selection using high-resolution melting analysis SNP genotyping primers as described (21). Homozygous progeny derived from mating heterozygous male and female ISCL mice that were free of background donor strain contamination were used to fix the lines.

GusbNull mice

GusbNull mice were obtained from Jackson Laboratory, as a mouse model of MPSVII. GusbNull mice were derived from heterozygous breeder pairs, and homozygous offspring were identified at markedly sub-Mendelian ratios (data not shown) by SNP genotyping and reduced body size. As per Jackson Laboratory documentation, this spontaneous mutant mouse line originally (data not shown) by SNP genotyping and reduced body size. The approximate 4174-bp fragment was excised, removed from the gel slice by electroelution in 3 ml of 1× TAE buffer run at 100 volts for 1 hour.

Purification of the CAG-Gusbb fragment. The transgenic fragment was removed from the backbone by cleavage with Earl and Spel restriction enzymes and separated by electrophoresis in 1× TAE buffer on a 1% agarose gel. The approximately 4174-bp fragment was excised, removed from the gel slice by electroelution in 3 ml of 1× TAE buffer run at 100 volts for 1 hour.

Arthritis analysis

Rear ankle joints were measured at the time of infection and at 4 weeks after infection by using a metric caliper, as described (19). Measurements of the thickest anteroposterior portion of the ankle with the joint extended were taken and are reported as the change in ankle swell.
ing over time. A histological assessment of arthritis severity was performed with the most swollen ankle joint. Tissues were fixed in 10% neutral buffered formalin, decalcified, embedded in paraffin, and cut into 3-μm-thick sections; sections were mounted onto glass slides and stained with H&E or with Alcian blue. The H&E-stained joint sections were evaluated blindly and scored for the severity of injury according to a subjective scale ranging from 0 to 5. A score of 0 indicated no lesions, and scores of 1, 2, 3, 4, and 5 indicated minimal, mild, moderate, marked, and severe lesions, respectively. The overall lesion score represented a combined assessment of neutrophil infiltration, mononuclear cell infiltration, tendon sheath thickness, and reactive-reparative responses. To assess GAG accumulation, joint sections from each group were given a subjective score based on the presence of Alcian blue-positive material in the soft tissue and joint/synovial space, ranging from 0 (none) to 4 (severe).

### Generation and analysis of radiation chimeras

Chimeras were generated in all pairwise combinations between B6 CD45.1 and B6.C3H-Blac2 (CD45.2) congenic mice as described (29). Briefly, 4-week-old mice were lethally irradiated with 2 doses of 252 CgY given 3 hours apart using a GE Isovolt Titan (GE Healthcare). 24 hours later, splenocytes were prepared from donor mice. Irradiated mice each received an intravenous injection of 10^8 splenocytes in a 200 μl volume. Chimerism was evaluated at 3 weeks after transplant by flow cytometric analysis of blood leukocytes (Supplemental Figure 6).

### K/BxN serum transfer

K/BxN serum was a gift from Paul Allen (Washington University). Rear ankle joints were measured with a metric caliper prior to treatment, as described above. 100 μl of K/BxN serum was administered by intraperitoneal injections on days 0 and 2. Ankle swelling was determined by measurements on days 1, 2, 4, and 7. After the final day 7 measurement, joint histopathology was assessed, as described above.

### Imaging of joint histology sections

Alcian blue-stained sections were visualized on an Olympus BX41 clinical imaging microscope (Olympus America) using ×4 total magnification. Images were recorded with an Olympus DP72 camera and prepared using Olympus cellSens digital imaging software.

### Statistics

All data represent mean ± SEM. All statistical calculations were performed using GraphPad Prism 5. P < 0.05 was considered statistically significant. Continuous variables were analyzed by 1-way ANOVA and Student’s t-test. Categorical variables were analyzed by Kruskal-Wallis or Mann-Whitney nonparametric tests. All calculations of Student’s t-tests and Mann-Whitney tests are 2-tailed unless otherwise specified.

### Study approval

All study protocols involving mice were conducted in accordance with the NIH guidelines for the care and use of animals and approved by the Institutional Animal Care and Use Committee at the University of Utah.

### Acknowledgments

We thank Mark Sands (Washington University) for providing the pCAGG-β-gluc mammalian expression plasmid that was used to create our transgenic overexpression construct. Paul Allen (Washington University) kindly provided K/BxN serum. The project described was supported by award T32AI055434 (to K.C. Bramwell), 6133/Arthritis Foundation (to K.C. Bramwell), AI32223/National Institute of Allergy and Infectious Diseases (NIAID) (to J.J. Weis), AR-43521/National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) (to C. Teuscher and J.J. Weis), NS061014/National Institute of Neurological Disorders and Stroke (NINDS) (to C. Teuscher), AI041747/NIAID (to C. Teuscher), NS060901/NINDS (to C. Teuscher), NS036526/NINDS (to C. Teuscher), and NS069628/NINDS (to C. Teuscher). The DNA/Peptide Core is supported in part by Cancer Center Support grant P30 CA04201. We thank Lynn Sonderegger and Robert Lochhead for helpful discussions. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.
