

Phenylketonuria

The In Vivo Hydroxylation Rate of Phenylalanine into Tyrosine Is Decreased

Abstract

In phenylketonuria (PKU), the enzyme phenylalanine hydroxylase is deficient, resulting in a decreased conversion of phenylalanine (Phe) into tyrosine (Tyr). The severity of the disease is expressed as the tolerance for Phe at 5 yr of age. In PKU patients it is assumed that the decreased conversion of Phe into Tyr is directly correlated with the tolerance for Phe. We investigated this correlation by an in vivo stable isotope study. The in vivo residual hydroxylation was quantitated using a primed continuous infusion of L-[ring-²H₅]Phe and L-[1-¹³C]Tyr and the determination of the isotopic enrichments of L-[ring-²H₅]Phe, L-[ring-²H₄]Tyr, and L-[1-¹³C]Tyr in plasma. Previous reports by Thompson and coworkers (Thompson, G.N., and D. Halliday. 1990. *J. Clin. Invest.* 86:317–322; Thompson, G.N., J.H. Walter, J.V. Leonard, and D. Halliday. 1990. *Metabolism.* 39:799–807; Treacy, E., J.J. Pitt, K. Seller, G.N. Thompson, S. Ramus, and R.G.H. Cotton. 1996. *J. Inherited Metab. Dis.* 19:595–602), applying the same technique, showed normal in vivo hydroxylation rates of Phe in almost all PKU patients. Therefore, our study was divided up in two parts. First, the method was re-evaluated. Second, the correlation between the in vivo hydroxylation of Phe and the tolerance for Phe was tested in seven classical PKU patients. Very low (0.13–0.95 $\mu\text{mol/kg}$ per hour) and normal (4.11 and 6.33 $\mu\text{mol/kg}$ per hour) conversion rates were found in patients and controls, respectively. Performing the infusion study twice in the same patient and wash-out studies of the labels at the end of the experiment in a patient and control showed that the method is applicable in PKU patients and gives consistent data. No significant correlation was observed between the in vivo hydroxylation rates and the tolerances. The results of this study, therefore, showed that within the group of patients with classical PKU, the tolerance does not depend on the in vivo hydroxylation. (*J. Clin. Invest.* 1998. 101:2875–2880.) Key words: diet • L-[ring-²H₅]phenylalanine • L-[ring-²H₄]tyrosine • L-[1-¹³C]tyrosine

Introduction

Phenylketonuria (PKU;¹ McKusick 261600) is caused by a deficiency of the hepatic enzyme phenylalanine hydroxylase (PAH; E.C. 1.14.16.1.). As a consequence phenylalanine (Phe) cannot be converted into tyrosine (Tyr; references 1, 2). Treatment aims at lowering the plasma Phe concentrations by dietary Phe restriction. The individual tolerance for Phe (i.e., the amount of Phe per kilogram body weight a patient can tolerate without achieving plasma Phe concentrations above a certain level) is used to define the severity of the disease (2, 3). Based on the tolerance for Phe at 5 yr of age, Güttler and Lou (3) distinguished three phenotypes, i.e., classical PKU, mild PKU, and persistent benign hyperphenylalaninemia (HPA).

It is more or less assumed that the differences in dietary tolerance for Phe are a direct consequence of the differences in individual ability to convert Phe into Tyr in patients with PKU and HPA. Various in vitro and in vivo studies have aimed at estimation of the individual ability to convert Phe into Tyr (4–7). The measurement of the in vitro enzyme activity, however, necessitates a liver biopsy. Treacy et al. (7), measuring the in vivo oxidation of Phe by use of an oral dose of L-[1-¹³C]Phe, show no clear correlation between the in vivo hydroxylation of Phe and the dietary tolerance for Phe within a specific class of PAH-deficient patients. As with most in vivo methods, however, this method is hampered by problems with quantitating the hydroxylation rate of Phe into Tyr (7).

With the method introduced by Clarke and Bier (8) real quantitation of the in vivo conversion rate of Phe into Tyr has become possible. This method is based on continuous infusion of the stable isotopically labeled tracers L-[ring-²H₅]Phe and L-[1-¹³C]Tyr, and shows consistent results in controls (8, 9).

Thompson and coworkers (9–11) applied a primed-continuous infusion technique of the stable isotopically labeled tracers L-[ring-²H₅]Phe, and L-[3,5-²H₂]Tyr in PKU and HPA patients. They calculated normal in vivo hydroxylation rates of Phe in 14 out of the 16 PKU patients in three successive studies, and no difference between the PKU and two HPA patients (9–11). These findings are at odds with all other in vitro and in vivo studies (4–7). Because of this highly unexpected observation, their data cast doubt upon the applicability of this primed-continuous infusion technique of stable isotopically labeled tracers of Phe and Tyr in PKU patients. Consequently, their data can not be included without hesitation in a study of relationship between the tolerance for Phe and the in vivo hydroxylation rate of Phe.

Therefore, the aim of this study was to answer two ques-

tions in classical PKU patients using the primed-continuous infusion technique of the stable isotopically labeled tracers L-[ring-²H₅]Phe, and L-[1-¹³C]Tyr. First, is it possible to calculate the in vivo hydroxylation rate of Phe from the isotopic enrichments in plasma during a primed continuous infusion protocol? Second, is there a correlation between the calculated in vivo hydroxylation of Phe into Tyr and the dietary tolerance for Phe in patients with classical PKU? The patients included in this study had dietary tolerances for Phe pointing at different severities within classical PKU.

Methods

Subjects

The studies were approved by the medical ethical committee of the University Hospital of Groningen. Informed consent was obtained from the individuals and/or their parents. Investigations were performed in two adult controls and seven patients. Patient 7 was investigated twice at different starting plasma Phe concentrations. The individual clinical details of the subjects are given in Table I. At the time of the tests all patients were free from intercurrent disease.

Patients were young with the exception of patient 7 who was 20 yr of age when he was studied for the second time. Diagnosis was based on the results of the neonatal screening and the classification according to Güttler and Lou (3). This classification divides between three phenotypes on the basis of the tolerance for Phe at 5 yr of age: classical PKU (tolerance < 20 mg/kg body weight per day), mild PKU (tolerance 20–50 mg/kg body weight per day), and persistent benign HPA (tolerance > 70 mg/kg body weight per day). The tolerances of Phe at 5 yr of age in the patients varied between 11 and 21 mg/kg body weight per day (Table I). Following the classification of Güttler and Lou (3) all but patient 1 clearly had the classical form of PKU. Patient 1 had a milder form of PKU. The same patient, however, has the classical form of PKU when the guidelines of the original study of Güttler are followed (12).

All patients were on a strict dietary treatment resulting in plasma Phe concentrations within the aimed range according to the therapeutic guidelines of Güttler and Lou at that time (3). The age- and sex-adjusted height for all patients was between the 10th and 90th percentile except for two patients, who had a height just below the

3rd percentile. The weight to height was between the 50th and the 90th percentile of the Dutch standards (13).

Measurement of hydroxylation rates

Isotopes. L-[ring-²H₅]Phe (98% ²H₅), L-[ring-²H₄]Tyr (98% ²H₄), and L-[1-¹³C]Tyr (98% ¹³C) were obtained from Cambridge Isotopes Laboratories (Andover, MA). Isotopes were infused in a solution of normal saline that was shown to be sterile and pyrogen free.

Procedure. Blood samples were taken 2–4 d before the test to calculate the amount of isotopes to be given in the priming doses. Controls were checked for heterozygosity of the PAH gene by measuring the Phe/Tyr ratio. The investigations were carried out in the metabolic ward of the Beatrix Children's Hospital and were started after an overnight fast. The study procedure closely resembled the procedure followed by Thompson et al. (9). During the test, the subjects received no food nor drink except for water. Before the test, two indwelling catheters were placed in the left and right brachial vein for infusion of the stable isotopes and blood sampling. The second catheter was kept open by an infusion of isotonic saline.

After collection of three baseline blood samples at time = –20, –10, and 0 min, subjects received a priming dose of L-[ring-²H₅]Phe (patients according equation 1, controls 2.9 μmol/kg) at time = 0 min, followed by a tracer dose (mean 4.33 ± 0.09 μmol/kg per hour, *n* = 8, SEM) during a total of 6 h, and a priming dose of L-[1-¹³C]Tyr (2.7 μmol/kg) at time = 60 min, followed by a continuous infusion of tracer (mean 4.20 ± 0.24 μmol/kg per hour, *n* = 8, SEM) for 5 h. Controls also received a priming dose of L-[ring-²H₄]Tyr (0.43 μmol/kg) at time = 0 min.

The priming dose *P* (in milligrams) of L-[ring-²H₅]Phe for patients was calculated exactly as described by Thompson and Halliday (9) according to equation 1:

$$P = \frac{[F] \times 0.5 \times BW}{100} \quad \text{EQUATION 1}$$

in which *[F]* is the Phe concentration in plasma in micromole per liter and *BW* is the body weight in kilograms. The factor 0.5 stands for the tracer infusion rate, since Thompson and Halliday infused 0.5 mg/kg per L-[ring-²H₅]Phe (9). This formula can be derived from the formula for the priming dose given by Wolfe (14). For the priming of the pool, the following equation 2 was derived (14):

$$P_w = \frac{[F] \times i_{2H5F} \times V}{R_{aF}} \quad \text{EQUATION 2}$$

in which *P_w* is the priming dose of L-[ring-²H₅]Phe in micromole per kilogram according to Wolfe, *i_{2H5F}* is the L-[ring-²H₅]Phe infusion rate in micromole per kilogram per hour, *V* is the volume of distribution of Phe in liters per kilogram and *R_{aF}* the rate of appearance of Phe in micromole per kilogram per hour.

P can be converted into *P_w* according to equation 3:

$$P = P_w \times BW \times \frac{165}{1000} \quad \text{EQUATION 3}$$

in which 165 is the molecular weight of Phe and 1,000 the conversion factor of micrograms into milligrams. Substituting equation 2 into equation 3, replacing the volume of distribution *V* with the value of 0.61 l/kg, and *R_{aF}* with a value of 10 mg/kg per hour results in equation 1 after some simple arithmetic.

Collection and analysis of samples

Blood samples were collected into heparinized tubes at 30-min intervals between 2 and 4 h and at 15-min intervals in the last 2 h of the studies. The total test procedure amounted to 6.5 h. Blood samples were immediately centrifuged for 5 minutes at 1,000 g. Plasma was stored at –20°C until analyzed.

For isotopic analysis, L-[ring-²H₅]Phe, L-[ring-²H₄]Tyr, and L-[1-¹³C]Tyr were derived to their corresponding *N*-acetyl,*O*-penta-fluoro-benzyl ester (15). Plasma (250 μl) was deproteinized and devoid

of anionic compounds by addition of HCl (0.1 N) and extracted twice with ethylacetate. The lower layers (water phase) were collected in a clean tube. To these collected layers a phosphate buffer (K_2HPO_4 – H_3PO_4 3 M, pH 8.5) was added to a final pH of above 7. The amino acids were *N*-acetylated by the addition of acetic anhydride under continuous vigorous agitation. Subsequently, the solution was brought to a pH of 3.0 by addition of HCl (6 N). The *N*-acetyl derivatives formed were extracted twice with ethylacetate. The upper layers (ethylacetate phase) were collected and evaporated to dryness under a gentle stream of nitrogen at 60°C. The pento-fluoro-benzyl esters were prepared by adding in sequence 5 μ l PFB-Br, 10 μ l triethylamine, and 50 μ l acetonitril. The derivative was washed with acidic ethylacetate. The ethylacetate layer was evaporated to dryness under a gentle stream of nitrogen at room temperature and to the residue ethylacetate was added.

Plasma L-[*ring*- 2H_5]Phe and L-[1- ^{13}C]Tyr isotope enrichments were measured with a Hewlett-Packard Model 5890 gas chromatograph (Amstelveen, The Netherlands) coupled to a VG Trio-II quadrupole mass spectrometer (Fisons, Manchester, United Kingdom). Electron capture negative ion ammonia chemical ionization was used. The analysis of L-Phe and L-Tyr was carried out on a CPSIL 5CB capillary fused silica column (Chrompack, Middelburg, The Netherlands), temperature programmed from 100°C to 275°C at 25°C minutes⁻¹. L-[*ring*- 2H_5]Phe eluted at 6.2 min and L-[1- ^{13}C]Tyr at 7.0 min. Phe was monitored at its base peak *m/z* 206 [M-167]⁻ and its 2H_5 labeled species at *m/z* 211, Tyr at its base peak *m/z* 264 [M-181]⁻, and its ^{13}C -labeled species at *m/z* 265.

L-[*ring*- 2H_4]Tyr plasma enrichment was measured with a Hewlett-Packard Model 5890 gas chromatograph coupled to a VG Analytical 70-250 S magnet sector mass spectrometer (Fisons). Electron impact ionization at 70 eV was used. The gas chromatography programming was operated as described above. L-Tyr eluted at 7.3 min and was monitored at its base peak *m/z* 344 [M-101]⁺ and its L-labeled species at *m/z* 348.

Plasma enrichments of L-[*ring*- 2H_5]Phe, L-[*ring*- 2H_4]Tyr, and L-[1- ^{13}C]Tyr were calculated from the intensity ratios of the labeled over unlabeled species using calibration curves. These curves were prepared from standard mixtures of weight amounts of labeled and unlabeled Phe and Tyr ranging from 0 to 10% mole fraction for L-[*ring*- 2H_5]Phe and L-[1- ^{13}C]Tyr, and from 0 to 0.1% mole fraction for L-[*ring*- 2H_4]Tyr when PKU patients were studied, and from 0 to 1% for controls.

Tracer model for phenylalanine and tyrosine kinetics

We used the model for Phe-Tyr metabolism as described by Clarke and Bier (8), with modifications as proposed by Thompson and Halliday (9). Briefly the flux of Tyr through the plasma compartment was calculated according to equation 4:

$$Q_Y = i_{CY} \left(\frac{E_i}{E_{CY}} - 1 \right) \quad \text{EQUATION 4}$$

where i_{CY} is the rate of L-[1- ^{13}C]Tyr infusion (micromole per kilograms per hour) and E_i and E_{CY} are the enrichments in mole percent excess of the infusate and plasma [1- ^{13}C]Tyr, respectively.

The rate of conversion of Phe (*F*) into Tyr (*Y*) ($Q_{F \rightarrow Y}$; micromole per kilograms per hour) was derived according to equation 5:

$$Q_{F \rightarrow Y} = Q_Y \frac{E_{DY}}{E_F} \quad \text{EQUATION 5}$$

where Q_Y is the Tyr flux through the plasma compartment, and E_{DY} and E_F are the plasma enrichments of L-[*ring*- 2H_4]Tyr and L-[*ring*- 2H_5]Phe.

Calculation of the hydroxylation rate of Phe into Tyr is based on the use of the isotopes L-[*ring*- 2H_5]Phe and L-[1- ^{13}C]Tyr, and the model of the Phe-Tyr metabolism as summarized in equation 5. In equation 5, it is assumed that there are no isotope effects and that the enrichment in plasma is similar to that in cytosol of the liver cells.

These assumptions about the isotope effect were recently under investigation (16–18). In general it appeared that these assumptions do not hold under all conditions. In our study, however, we compared the hydroxylation rate of patients and controls and compared them to literature data, in which the same methodology and isotopes were used giving differences in isotopes and intracellular dilution.

Plasma Phe and Tyr concentrations were determined in plasma using an ion exchange liquid chromatography amino acid analyzer (Carlo Erba 3A30; Interscience, Breda, The Netherlands). In our laboratory modifications resulted in a coefficient of variation of this method of 2%.

Statistical analyses were performed using the Student's *t* test for testing the statistical significance of the difference in hydroxylation rates between controls and patients and within the studied group of patients. We used the Kendall's ranking correlation test for testing the statistical significance of a correlation between the tolerance for Phe at 5 yr of age and the in vivo hydroxylation rate.

Results

In all patients plateau plasma enrichments were achieved for both L-[*ring*- 2H_5]Phe, L-[1- ^{13}C]Tyr, and L-[*ring*- 2H_4]Tyr in < 2 h. In Fig. 1, A–C, the mean plasma enrichments are presented for L-[*ring*- 2H_5]Phe, L-[1- ^{13}C]Tyr, and L-[*ring*- 2H_4]Tyr, respectively.

In the controls plateau enrichment was achieved in < 2 h for all isotopes but L-[*ring*- 2H_4]Tyr (results not shown). The enrichments of L-[*ring*- 2H_5]Phe and L-[*ring*- 2H_4]Tyr in controls (Table II) were similar to those reported previously (8–10, 16, 17). The enrichments of L-[1- ^{13}C]Tyr in controls and patients were twice as high as reported in controls by others (8, 16) because of higher infusion rates in our study protocol. The enrichments of L-[*ring*- 2H_4]Tyr in our patients were extremely low if compared with controls in this study and other studies

(8–10, 16, 17), as well as patients studied by two of the studies of Thompson et al. (9, 10), while no information was given in a third study (11).

Following the analytical methods of Thompson and Halliday (9) using an electron-impact ionization on a quadrupole mass spectrometer (9), reliable measurements of the enrichment of L-[ring-²H₄]Tyr were not possible. This was caused by a combination of the very low enrichment of the tracer and a high level of background noise due to unknown compounds that could not be resolved from the Tyr peak by this method. We, therefore, had to refine the analytical methods for isotopic analyses of L-[ring-²H₄]Tyr. After trying several other methods, the samples were derivatized to their corresponding *N*-acetyl, *O*-penta-fluoro-benzyl ester, following the analytical methods of de Jong et al. (15). This way we could obtain a reproducible and quantifiable signal with a sector magnet instrument in electron impact ionization mode, resulting in reliable measurements of the enrichment of L-[ring-²H₄]Tyr.

To further determine the appropriateness of the measurements of L-[ring-²H₄]Tyr, we determined the extent of wash out of label 30 min after the infusion of isotopes had been stopped in a patient and control. In the patient the mole percent enrichments of L-[ring-²H₅]Phe, L-[1-¹³C]Tyr, and L-[ring-²H₄]Tyr decreased from 4.3 to 3.9%, from 4.7 to 2.0%, and from 0.042 to 0.038%, respectively. In the control these values decreased from 5.7 to 1.4%, from 3.9 to 1.3%, and from 0.78 to 0.42%, respectively. In both the patient and control, the decrease of the enrichment of L-[1-¹³C]Tyr was of the same mag-

nitude. The similarity of the decreases of the enrichments of L-[ring-²H₅]Phe and L-[ring-²H₄]Tyr in the PKU patient suggests a precursor-product relationship between the metabolites indicating that we indeed measured L-[ring-²H₄]Tyr. To test the reproducibility of the measurements we performed the study twice in one patient. In both studies the measured enrichments were comparable notwithstanding different plasma Phe values at the start of the studies (Tables I and II).

The calculated rates of the in vivo hydroxylation of Phe into Tyr were 6.33 and 4.11 $\mu\text{mol/kg}$ per hour in the two healthy individuals, being comparable to the values found by others using comparable methods (8–10, 16, 17). Since the calculated hydroxylation rate of Phe into Tyr linearly depends on the enrichment of L-[ring-²H₄]Tyr, the hydroxylation rates of Phe into Tyr were low in all patients, varying between 0.13 and 0.95 $\mu\text{mol/kg}$ per hour (Table II). These hydroxylation rates are statistically significantly different from normal ($P < 0.001$). Next to this, within the studied group of patients with classical PKU the in vivo hydroxylation rate of patient 5 was statistically significantly different from the hydroxylation rate in the other patients ($P < 0.01$; Table II). This difference in hydroxylation rate, however, did not result in a higher tolerance for dietary Phe in the patient. In the studied group of patients, no correlation was observed between the tolerance for Phe and the in vivo hydroxylation rate of Phe. At the studied plasma Phe concentrations, no relationship could be observed between the hydroxylation rate and the basal Phe concentration (Fig. 2).

Figure 2. Relationship between plasma phenylalanine concentrations (micromole per liter) and hydroxylation in PKU patients (micromole per kilogram per hour).

Discussion

Thus far, it has been tacitly assumed that the estimation of the residual *in vivo* PAH activity directly relates to the empirically estimated tolerance for dietary Phe at 5 yr of age. Using a bolus of oral L-[1-¹³C]Phe Treacy et al. (7) found no clear correlation between the oxidation rate of Phe and the dietary tolerance for Phe within a specific class of PAH-deficient patients, but quantitation of the *in vivo* Phe hydroxylation with this method is difficult. In this study, the relationship between the *in vivo* PAH activity and the tolerance for dietary Phe was tested by means of a primed continuous infusion of stable isotopically labeled tracers. This technique is validated in healthy humans (8, 9), and promises to present reliable estimates of the residual *in vivo* PAH activity in PKU patients. Using this method, Thompson and coworkers calculated normal *in vivo* hydroxylation rates in most PKU patients and 2 HPA patients (9–11), which is in disagreement with all other studies (4–7), and therefore cast doubt upon the applicability of this method to measure the hydroxylation rate in PKU and HPA patients.

In this study, first the method was re-evaluated in PKU patients before the relationship could be tested between the tolerance for dietary Phe and the *in vivo* hydroxylation of Phe into Tyr. We calculated several decreased hydroxylation rates in all our patients with classical PKU (Table II), which is in accordance with both *in vitro* and *in vivo* studies (4–7). The appropriateness of our measurements is underlined by the wash out studies in both the patient and control, while the reproducibility is shown by the similar hydroxylation rates when measured twice in the same patient (Table II).

While the results of the studies of Thompson and coworkers (9–11) and our study are different, part of the discussion must focus on differences with respect to the subjects, the strictness of dietary treatment, the test procedure, and the analysis of the isotopic enrichments, the calculations being exactly the same.

Concerning the studied patients, the ages at the time of the study in both of our studies show some overlap, while the severity of the PKU patients is comparable (9–11), although two of the other patients of Thompson et al. had HPA (9). One of the most striking differences is the strictness in dietary treat-

ment. Most of Thompson and coworkers' patients were on a diet described as "relaxed strict dietary control" (9–11), some of them having intakes above the requirements advised in the recommended dietary allowances (19). In our study, six out of the seven studied patients were on a very strict dietary regimen. This difference in dietary Phe intakes resulted in differences in the actual plasma Phe concentrations between their study and our study—the patients of Thompson and coworkers (9–11) had higher Phe concentrations (mean Phe 1032 $\mu\text{mol/l}$, SEM 87 $\mu\text{mol/l}$) than in our study (mean Phe 419 $\mu\text{mol/l}$, SEM 27 $\mu\text{mol/l}$). Thompson et al. (9, 10) hypothesized that the normal hydroxylation rates in their studies were caused by high plasma Phe concentrations. However, neither their results nor ours showed evidence to support such a concentration dependency of the hydroxylation rate (Fig. 2; references 9–11).

Regarding the test procedure, differences exist in the protocol with respect to the amount and the type of the given isotopes. Compared with the studies of Thompson and coworkers (9–11), the continuous infusion of L-[ring-²H₅]Phe in our study was some 1.5 times higher to be able to measure the anticipated very low isotopic enrichments of Tyr with L-[ring-²H₄]Tyr. With regards to the measurements of the turnover of Tyr, we used L-[1-¹³C]Tyr, while Thompson and coworkers (9–11) used L-[3,5-²H₂]Tyr. Thompson and coworkers calculated turnover rates of Tyr in the patients which were about half the turnover reported in our study. The results in our patients are in line with the healthy adults of both our study and Clarke and Bier's study (8). This is important in view of equation 5 used to calculate the *in vivo* hydroxylation of Phe, in which the hydroxylation rate is proportional to the correction for the turnover of Tyr. Therefore, on the basis of the turnover rates, one would expect the hydroxylation rates in their studies to be lower than in our studies. In contrast, in our study the normal turnover of Tyr coincided with extremely low *in vivo* hydroxylation rates.

Concerning analytical differences between the studies of Thompson and coworkers (9–11) and our studies, it was already discussed that in our patients quantitation of the enrichments of L-[ring-²H₄]Tyr using the method described by Thompson and Halliday (9) was difficult. However, the use of the method of de Jong et al. (15) allowed for the measurement of the extremely low enrichments of L-[ring-²H₄]Tyr in our patients in a reliable way.

The results of our study showed that the *in vivo* hydroxylation of Phe may vary within the group of patients with classical PKU, but that this does not necessarily result in different tolerances, while different tolerances did not correlate with the *in vivo* hydroxylation rates within this studied group of patients with classical PKU.

A lack of correlation between the *in vivo* hydroxylation of Phe and the tolerance for Phe may be due to several causes. First, the investigated PKU patients may have shown too little heterogeneity to find a possible correlation. Other studies reported high correlations between the tolerance and both the *in vitro* mutation expression in cultured mammalian cells and the oxidation rate of L-[1-¹³C]Phe (7, 20–22), but the groups of the patients ranged from the most severe form of PKU to the mildest form of HPA. If the data were re-analyzed for the group of patients with classical PKU, the results showed no correlation between the tolerance and the measured residual PAH activity (7, 20).

Secondly, the tolerance for dietary Phe is the result of a combination of the in vivo hydroxylation rate, day to day variables, patient-dependent, and doctor-dependent factors. Day-to-day variables, such as intercurrent illness, energy and total protein intake, influence the balance between the catabolic and the anabolic state. Years ago, Güttler et al. (23) showed that the plasma Phe concentration rises during the night. This observation was confirmed by our studies showing that the Phe concentration rises during the night and during the morning if breakfast is omitted (24, 25). We reasoned that this effect is due to net protein catabolism (25). The patient-dependent variables include factors such as growth, and the compliance to the prescriptions, while the doctor-dependent variables include factors such as the prescribed amount of total protein, amino acid mixture (26) and energy, and the target Phe concentration (24). All these three causes, and a combination of all three, may explain the lack of correlation between the tolerance for Phe at 5 yr of age and the in vivo hydroxylation rate of Phe in PKU patients in our study.

In conclusion, the results of this study showed that the primed-continuous infusion technique with stable isotopically labeled tracers is applicable in PKU patients and showed a clearly decreased in vivo conversion of Phe into Tyr in patients with classical PKU. The results of this study confirmed the results of in vitro and in vivo studies in PKU showing a decreased hydroxylation rate in PKU patients (4–7). The results of this study show that the defect in hydroxylation in these patients can be measured in vivo both by giving L-[1-¹³C]Phe and L-[ring-²H₅]Phe. The results are in contrast with the normal hydroxylation rates of the studies of Thompson and coworkers (9–11). The different hydroxylation rates between their and our results can not be explained by differences in the patients or methods between their and our studies. In our study, a difference in hydroxylation rate was found in one of the patients with classical PKU compared with the others. No correlation was found between the tolerance for Phe at 5 yr of age and the in vivo hydroxylation rate of Phe in patients with classical PKU. The results of this study, therefore, showed that within the group of patients with classical PKU, the difference in tolerance does not correlate with the in vivo hydroxylation. Further studies are necessary to explain the differences in results with the studies of Thompson and coworkers (9–11). In addition, further studies are necessary to investigate whether a correlation between the tolerance and the in vivo hydroxylation rate of Phe exists when patients are included with tolerances pointing at less severe forms of the PAH deficiency.

Acknowledgments

The authors express their gratitude to Mr. T. van Dijk, Mrs. M. van Rijn, Mrs. I. Mulder, Mr. T. de Jong, Mr. W. van Eck, and Dr. E.Th.H.G.J. Oremus for technical and dietary assistance, and preparing the solutions with the stable isotopes.

Financial support was obtained from the “Hendrik de Cock Stichting” from the University Hospital of Groningen and the “Stichting Erfelijkheidsvoorlichting.”
