The proteasome inhibitor bortezomib has been successfully used to treat patients with relapsed multiple myeloma; however, many of these patients become thrombocytopenic, and it is not clear how the proteasome influences platelet production. Here we determined that pharmacologic inhibition of proteasome activity blocks platelet formation in human and mouse megakaryocytes. We also found that megakaryocytes isolated from mice deficient for PSMC1, an essential subunit of the 26S proteasome, fail to produce proplatelets. Consistent with decreased proplatelet formation, mice lacking PSMC1 in platelets (Psmc1fl/fl Pd4-Cre mice) exhibited severe thrombocytopenia and died shortly after birth. The failure to produce proplatelets in proteasome-inhibited megakaryocytes was due to upregulation and hyperactivation of the small GTPase, RhoA, rather than NF-κB, as has been previously suggested. Inhibition of RhoA or its downstream target, Rho-associated protein kinase (ROCK), restored megakaryocyte proplatelet formation in the setting of proteasome inhibition in vitro. Similarly, fasudil, a ROCK inhibitor used clinically to treat cerebral vasospasm, restored platelet counts in adult mice that were made thrombocytopenic by tamoxifen-induced suppression of proteasome activity in megakaryocytes and platelets (Psmc1fl/fl Pdag-Cre-ER mice). These results indicate that proteasome function is critical for thrombopoiesis, and suggest inhibition of RhoA signaling as a potential strategy to treat thrombocytopenia in bortezomib-treated multiple myeloma patients.

Introduction

Thrombocytopenia (low platelet count) is observed in numerous diseases and can be life threatening due to bleeding complications. Bortezomib, a reversible chemotherapeutic inhibitor used to treat patients with relapsed multiple myeloma, often induces thrombocytopenia within a few days of therapy initiation (1–3). Bortezomib-induced thrombocytopenia is dose-limiting, and if severe, bortezomib is withheld (2, 3). Although the mechanisms by which bortezomib induces thrombocytopenia is not clear, its primary mode of action is inhibition of the proteasome. The clinical observation that platelet counts rise above pretherapy levels upon cessation of bortezomib treatment suggests that bortezomib affects thrombopoiesis (1, 3).

Like other cells, megakaryocytes and anucleate platelets possess proteasome activity (4, 5). While the specific functions of the proteasome in platelet precursors (e.g., megakaryocytes) is relatively unknown (6), there is evidence that bortezomib alters the function of platelets (7–11). It has also been hypothesized, but not proven, that bortezomib inhibits megakaryocyte development via nuclear factor xB (NF-κB) (12). The aim of the present work was to precisely define the roles of the proteasome in thrombopoiesis and, in doing so, determine whether bortezomib-induced thrombocytopenia can be reversed. Using a combination of pharmacologic and genetic tools, we showed that inhibition of proteasome activity in megakaryocytes blocks proplatelet formation. In addition, conditional deletion of proteasome activity in mouse megakaryocytes led to severe thrombocytopenia and postnatal death. Decreased thrombopoiesis in proteasome-inhibited mice was caused by accumulation and increased activity of RhoA, and inhibitors of the RhoA signaling pathway restored platelet production. These findings demonstrated that the megakaryocyte proteasome controls the final stages of platelet production and also provided a potential option for restoring platelet counts in thrombocytopenic patients treated with bortezomib.

Results

Pharmacologic inhibition of the proteasome blocks platelet production. Due to its thrombocytopenic side effects, bortezomib is typically administered as a bolus twice weekly for 2 weeks (days 1, 4, 8, and 11), followed by a 10-day rest period (3). To ascertain the immediate effects of this inhibitor on platelets, mice were administered a clinically relevant dose (2 mg/kg body weight) of bortezomib, and platelet counts and proteasome activity were measured. Consistent with its well-known effect on platelet counts in patients, bortezomib induced a mild thrombocytopenia within 24 hours of...
treatment (Figure 1A). The thrombocytopenia was transient and temporally correlated with inhibition of proteasome activity in circulating platelets (Figure 1A).

To assess whether bortezomib-induced thrombocytopenia was due to accelerated clearance, we injected Dylight 488 conjugated to GPIBβ into the bloodstream to track the lifespan of platelets in vivo in the presence of bortezomib or its vehicle. As expected, the number of labeled platelets decreased over 96 hours as platelets were cleared from the circulation (13). However, the number of labeled platelets was similar between bortezomib and vehicle treatment groups at every time point tested (Figure 1B). This suggested that bortezomib did not induce platelet activation in the bloodstream, which would facilitate platelet clearance. Consistent with this notion, we found that bortezomib did not directly induce activation of integrin αIIbβ3 (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI75247DS1), nor did it alter agonist-induced activation of integrin αIIbβ3, or surface expression of P-selectin in mouse platelets (Supplemental Figures 1 and 2). Similarly, bortezomib did not influence PAC-1 binding to human platelets in the presence or absence of agonist stimulation (Supplemental Figure 3 and data not shown).

Since acute administration of bortezomib did not shorten the lifespan of circulating platelets, we hypothesized that the bortezomib-induced thrombocytopenia was due to a decrease in platelet production. To test this, we depleted platelets with an antibody against GPIBa and then treated mice with bortezomib and examined the expression of nuclear factor of κ light polypeptide gene enhancer in B cells inhibitor, α (IκBα), which induces IκBα protein levels (5). Based on this published work, and our present finding that inhibition of the proteasome decreased proplatelet formation in murine megakaryocytes. Bortezomib significantly decreased proplatelet formation in fetal liver-derived megakaryocytes (Figure 2A). Similar responses were observed in human megakaryocytes, and removal of bortezomib from the incubation media restored proplatelet formation (Figure 2B and data not shown). To confirm that this effect was specific to proteasome inhibition, megakaryocytes were treated with MG132 or lactacystin. Both proteasome inhibitors phenocopied the effects of bortezomib (Supplemental Figure 4 and data not shown). The inability to form proplatelets was accompanied by a notable increase in cell spreading on immobilized fibrinogen (Figure 2B), which indicates that the proteasome regulates key cytoskeletal proteins in megakaryocytes.

**Phenotypic consequences of proteasome inhibition are independent of NF-κB and integrin αIIb.** Bortezomib’s antitumor activity in multiple myeloma has been attributed to inhibition of NF-κB in plasma cells (14). Therefore, others have speculated that proteasome inhibitors may induce thrombocytopenia via the NF-κB signaling pathway (12). To test this hypothesis, we first treated megakaryocytes with bortezomib and examined the expression of nuclear factor of κ light polypeptide gene enhancer in B cells inhibitor, α (IκBα), which sequesters NF-κB in the cytoplasm until it is phosphorylated, ubiquitinated, and degraded (15). As expected, bortezomib increased the expression of IκBα in megakaryocytes (Figure 3A), which demonstrated that inhibition of the proteasome blocks the NF-κB signaling pathway. We also found that inhibition of IκB kinase with SC-514, which induces IκBα phosphorylation, increased IκBα protein levels in megakaryocytes (Figure 3A). However, unlike bortezomib, SC-514 did not halt proplatelet production (Figure 3B).

In addition to regulating NF-κB activity, Mitchell and colleagues previously demonstrated that the proteasome is capable of degrading pro-integrin αIIb (5). Based on this published work, and our present finding that inhibition of the proteasome decreased
the formation of proplatelets when megakaryocytes adhere to fibrinogen, we sought to determine whether bortezomib regulated the activity of integrin \(\alpha_f\beta_3\) in megakaryocytes. Bortezomib did not alter the expression of mature integrin \(\alpha_f\beta_3\) protein, nor did it increase binding of soluble fibrinogen or PAC-1 to human megakaryocytes (Supplemental Figure 5 and data not shown). Bortezomib also had no effect on adherence of human megakaryocytes to fibrinogen (Supplemental Figure 6). Together, these data indicate that bortezomib does not directly block proplatelet formation through NF-kB–or integrin \(\alpha_f\beta_3\)–dependent mechanisms.

**Phenotypic consequences of proteasome inhibition require RhoA.** The changes in actin polymerization observed in megakaryocytes treated with proteasome inhibitors were reminiscent of cytoskeletal changes in endothelial cells that rely on the small GTPase RhoA (16). Indeed, we found that bortezomib increased total RhoA protein expression (Figure 4A). Bortezomib also increased RhoA-GTP activity and phosphorylation of myosin light chain (MLC) kinase, which is downstream of RhoA (Figure 4, A and B).

RhoA-dependent signaling has been linked to the production of proplatelets (17, 18). Therefore, we treated human megakaryocytes with Y27632, a selective inhibitor of the Rho-associated protein kinase p160ROCK, or with C3 transferase, a direct RhoA inhibitor. Y27632 and C3 transferase rescued proplatelet formation in bortezomib-treated cells (Figure 4C and Supplemental Figure 7). This response was likely due to inhibition of downstream RhoA effectors, because Y27632 decreased phosphorylation of MLC kinase in the presence of bortezomib (Figure 4B). In agreement with the rescue of proplatelet formation observed in bortezomib-treated human megakaryocytes, mouse megakaryocytes treated with bortezomib plus Y27632 or with bortezomib plus fasudil, a more clinically relevant p160ROCK inhibitor, formed proplatelets (Figure 4D). These results in mouse megakaryocytes were similar to a recent report by Murai et al. (19).

**Genetic deletion of the proteasome results in severe thrombocytopenia and death.** To further dissect the role of the proteasome in thrombopoiesis, we focused on protease (prosome, macropain) 26S subunit, ATPase 1 (Psmc1; gene ID 19179) in mouse megakaryocytes and platelets. Psmc1 is an essential subunit of the 19S regulatory particle that is critical for ubiquitin-mediated protein degradation by the 26S proteasome complex (20–22). It is conserved at the protein level in human and mouse megakaryocytes (Supplemental Figure 8). mRNA for Psmc1 was also expressed in both species, although human megakaryocytes had lower levels of the transcript compared with mouse megakaryocytes (Supplemental Table 1).

Psmc1–/– mice were crossed with platelet factor 4 Cre recombinase (Pf4-Cre) mice to disrupt proteasome activity in megakaryocytes and platelets. Psmc1–/– Pf4-Cre mice had significantly reduced protein for PSMC1 in megakaryocytes, but not other tissues (Supplemental Figure 9). Ubiquinated proteins also accumulated in megakaryocytes from Psmc1–/– Pf4-Cre mice (Supplemental Figure 10).

Despite a marked reduction in PSMC1 protein, the number of megakaryocytes from Psmc1–/– Pf4-Cre mice in bone marrow or spleen was not reduced compared with Psmc1+/+ mice (Supplemental Figure 11). Unlike their littermate controls, however, Psmc1–/– Pf4-Cre mice had severe thrombocytopenia at postnatal day 1 (P1), and the majority of Psmc1–/– Pf4-Cre mice died before weaning (Figure 5, A and B). The reduction in platelet counts was more severe than in c-Mpl knockout pups at the same age (Supplemental Figure 12). In addition to reduced numbers of platelets, Psmc1–/– Pf4-Cre mice had lower hematocrits than Psmc1+/+ mice, and bleeding was seen in the abdomen and limbs (Figure 5, C and D). Pathological signs of hemorrhage were also present in the bladder and testes of all animals and occasionally observed in the brain, lymph nodes, and intestines (Figure 5E and data not shown).

**Ultrastructure examination of megakaryocytes from Psmc1–/– Pf4-Cre mice revealed less cytoplasm compared with megakaryocytes from Psmc1+/+ mice (Figure 6A). In addition, Psmc1–/– Pf4-Cre megakaryocytes lacked demarcation membranes, which were readily visible in Psmc1+/+ megakaryocytes (Figure 6A). Similar to mouse megakaryocytes treated with bortezomib (Figure 2A), megakaryocytes from Psmc1–/– Pf4-Cre mice failed to produce proplatelets (Figure 6B).**

**Inhibition of RhoA-dependent signaling prevents thrombocytopenia induced by genetic disruption of proteasome activity.** As predicted from the pharmacological data, megakaryocytes from Psmc1–/– Pf4-Cre mice expressed higher levels of total RhoA protein and RhoA-GTP.
Psmc1fl/fl Pdgf-Cre-ER mice were used because Pdgf-Cre-ER receptor (Pdgf-Cre-ER) mice, which allowed for time-restricted deletion of Psmc1 in megakaryocytes and platelets after administration of the competitive estrogen receptor ligand tamoxifen. Although Pdgf is expressed by other cells besides megakaryocytes, Pdgf-Cre-ER mice were used because Pdgf-Cre-ER mouse lines are not currently available. Like Psmc1fl/fl Pf4-Cre mice (Figure 5, A and B), administration of tamoxifen to Psmc1fl/fl Pf4-Cre-ER mice at P1 resulted in thrombocytopenia and early postnatal mortality (Supplemental Figure 13, and pro–integrin αIIbβ3 and translocation of P-selectin to the surface of platelets. When tamoxifen was administered to adult Psmc1fl/fl Pdgf-Cre-ER mice, platelet counts were reduced by approximately 50% after 6 days compared with Psmc1fl/fl mice (Figure 8A). In the presence of fasudil, however, tamoxifen did not significantly decrease platelet counts in Psmc1fl/fl Pdgf-Cre-ER mice (Figure 8A). Consistent with these rescue experiments, staining of megakaryocytes in crude bone marrow showed that the in vivo fasudil treatment rescued proplatelet formation (Figure 8B). These results are consistent with our in vitro findings that fasudil maintained proplatelet formation in bortezomib-treated megakaryocytes (Figure 4D).

Discussion

In this study, we found that pharmacologic or genetic disruption of proteasome activity in megakaryocytes inhibits proplatelet formation. Pharmacologic inhibition was reversible in megakaryocytes treated in vitro with bortezomib, and thrombocytopenia was transient when bortezomib was administered as a bolus in vivo. When inhibition of proteasome activity was sustained, as was the case with genetic deletion of Psmc1 in megakaryocytes and platelets, megakaryocytes did not form proplatelets, and Psmc1fl/fl Pf4-Cre mice had severe thrombocytopenia. Mice with genetic ablation of Psmc1 in megakaryocytes and platelets also died shortly after birth. Taken together, these data provide compelling evidence that the proteasome is critically involved in thrombopoiesis. The data also offer a strong explanation as to why multiple myeloma patients require cyclic treatment regimes of bortezomib in order to tolerate the drug (3, 12).

Our findings provide definitive proof that the megakaryocyte proteasome is required for the final stages of platelet production. Evidence for this is 2-fold: first, pharmacologic inhibition of proteasome activity in late-stage human or mouse megakaryocytes significantly blunted proplatelet formation; and second, platelet production was significantly reduced in Psmc1fl/fl Pf4-Cre mice, in which genetic deletion of Psmc1 does not occur until megakaryocytes express platelet factor 4, which activates the Cre recombinase (23). In addition to regulating thrombopoiesis, others have shown that the proteasome is important for the proliferation of megakaryocyte precursors (24) and the degradation of cyclin B and pro–integrin αIIbβ3 in megakaryocytes (5, 25).

Like their parent megakaryocytes, anucleate platelets also possess proteasome activity (4, 10), and several groups have demonstrated that pharmacologic inhibition of the proteasome regulates platelet function (8–11, 26). Under the conditions of our experiments, bortezomib did not affect indices of platelet activation in mouse or human platelets that included activation of integrin αIIbβ3 and translocation of P-selectin to the surface of platelets. However, similar to Gupta and coworkers (8), we observed that bortezomib reduced the aggregation of human platelets when low concentrations of thrombin were used as the agonist (Supplemental Figure 14). Although more work is needed, results generated by multiple independent groups strongly indicate that protein degradation systems regulate platelet function (6).

Other groups have shown that pharmacologic inhibition regulates the function of platelets ex vivo (8–11, 26), but bortezomib did not accelerate the clearance of labeled platelets under the conditions of our present studies. Our results contrasted those of Nayak and colleagues (7), who showed that pharmacologic inhibition of the proteasome reduced the half-life of platelets in mice. One potential explanation for these discordant findings is that the bolus dose of bortezomib used in our studies only produced a mild thrombocytopenia and did not completely ablate platelet proteasome activity (Figure 1A). Although Nayak’s group did not measure cellular proteasome activity (7), it is possible that they achieved more efficient pharmacologic inhibition of the proteasome in platelets and other vascular cells. Different routes of drug administra-

**Figure 4.** The proteasome regulates proplatelet formation through the RhoA signaling pathway. (A) Human megakaryocytes were treated with vehicle or bortezomib, and total RhoA and GTP-bound RhoA were measured. Shown are representative Western blots and expression of RhoA or RhoA-GTP, as measured by densitometry, relative to vehicle control. Data are mean ± SEM of 4 independent experiments. (B and C) Human megakaryocytes were treated with vehicle, bortezomib, or bortezomib plus Y27632. (B) Western blot for phospho-MLC. (C) Representative confocal images of human megakaryocytes stained with WGA (red) and phalloidin (green). Arrows denote proplatelets. Scale bar: 50 μm. Also shown is the number of proplatelet-producing megakaryocytes relative to vehicle control. Data are mean ± SEM of 3 independent experiments. (D) Representative transmission images of mouse bone marrow–derived megakaryocytes treated with vehicle, bortezomib, bortezomib plus Y27632, or bortezomib plus fasudil. Scale bar: 100 μm. Also shown is the number of proplatelet-producing megakaryocytes relative to vehicle control. Data are mean ± SEM of 3 independent experiments. *P < 0.05 vs. vehicle; **P < 0.05 vs. bortezomib alone.

We found that thrombocytopenia was more severe in Psnc1fl/fl Pf4-Cre mice compared with c-Mpl knockout mice (Supplemental Figure 12), which have normal life expectancies (27). Consistent with a marked reduction in platelet counts, Psnc1fl/fl Pf4-Cre mice had low hematocrits and hemorrhaging in the abdominal region. Occasional hemorrhaging was also observed in the brain, lymph nodes, and intestines. This suggests that severe thrombocytopenia is the primary driver of postnatal death in Psnc1fl/fl Pf4-Cre mice. Hemorrhaging in Psnc1fl/fl Pf4-Cre mice may occur because platelet numbers are simply too low to prevent bleeding. Alternatively, insufficient platelet counts in Psnc1fl/fl Pf4-Cre mice may result in abnormal vascular development or blood/lymphatic vessel separation, which could lead to excessive bleeding (28). In this regard, several groups have shown that platelet C-type lectin-like receptor 2 (CLEC-2) receptors regulate lymphatic vascular development, and, like Psnc1fl/fl Pf4-Cre mice (29–33), platelet-specific knockout of CLEC-2 results in postnatal lethality (32). It should also be noted that a very low threshold of platelet function sufficiently maintains vascular function (27, 33, 34), raising the possibility that Psnc1fl/fl Pf4-Cre mice produce dysfunctional platelets that are incapable of maintaining vascular integrity. Indeed, recent studies have demonstrated that immune-type receptors in platelets are critical for the prevention of inflammation-induced hemorrhage (35). Thus, it is entirely possible that in addition to being reduced in number, platelets from Psnc1fl/fl Pf4-Cre mice express an abnormal repertoire of proteins resulting in platelet dysfunction.

Studies in megakaryocytes revealed that genetic or pharmacologic interruption of proteasome activity led to accumulation of IkBα and RhoA. Although both proteins were upregulated, we found that the final stages of proplatelet formation required RhoA signaling rather than inhibition of NF-κB, as previously suggested (12). The inability to sprout proplatelets resembled studies in neu-
rons, in which acute inhibition of the proteasome blocks activity-dependent growth of new dendritic spines. It is not known what proteins are degraded by the proteasome in order to stimulate new spine growth; however, inactivation of RhoA leads to neurite outgrowth (36, 37). This suggests that, similar to megakaryocyte proplatelet formation, the proteasome may control neuronal outgrowth by degrading RhoA. Moreover, RhoA signaling has been shown to maintain normal megakaryocyte development, which is critical for platelet production (18).

Malfunction of the proteasome in human diseases may lead to aberrant platelet production or abnormal platelet generation. Disruption of proteasome activity could occur at multiple checkpoints, since human megakaryocytes expressed the full repertoire of proteasome components at the mRNA level (Supplemental Table 1). Identifying the complete portfolio of target proteins degraded by the proteasome in megakaryocytes will shed additional light on the mechanisms that control thrombopoiesis and the phenotype of platelets as they enter the circulation. Understanding the functions of the proteasome in platelets, which is active and capable of degrading proteins (7–9), also requires further investigation. From an immediate perspective, our present findings demonstrated that bortezomib directly inhibits proteasome activity in megakaryocytes and thereby decreases platelet production. Our findings also established fasudil as a potential treatment for preventing and/or reversing bortezomib-induced thrombocytopenia in multiple myeloma patients. Additionally, inhibitors of the RhoA signaling pathway may have efficacy in the treatment of other thrombocytopenic disorders caused by abnormal platelet production, especially if the disease is driven by proteasome-dependent mechanisms.
Methods

Differentiation of human and mouse megakaryocytes

Cord blood from normal full-term deliveries was obtained, and CD34+ hematopoietic progenitors were isolated and differentiated into megakaryocytes as previously described (38, 39). Mature megakaryocytes were placed on immobilized human fibrinogen-coated surfaces in the presence of specific inhibitors or their vehicle, and the number of megakaryocytes that possessed proplatelets was counted by an independent blinded observer. On average, 12% ± 3% of vehicle-treated fetal liver–derived megakaryocytes had proplatelet extensions.

Mouse megakaryocytes were isolated from fetal liver as previously described (40). Mouse bone marrow–derived megakaryocytes were obtained using modifications of a published report (41). For the bone marrow megakaryocytes, C57BL/6 mice (8-10 weeks of age) were euthanized, and cells were obtained from the bone marrow of femur and tibia by flushing the bone marrow. Cells were homogenized by pipetting followed by passage through a 100-μm filter. The cell population was resuspended in 10% fetal bovine serum–supplemented DMEM with 2 mM L-glutamine, penicillin/streptomycin, and fibroblast condition media containing thrombopoietin. The cells were cultured for 5 days (37°C and 5% CO2), and mature megakaryocytes were layered over a bovine serum albumin (BSA) gradient as described previously (42). Fetal liver and bone marrow–derived megakaryocytes were subsequently resuspended in culture media as described above, then placed on immobilized BSA or fibrinogen in the presence or absence of inhibitors, and megakaryocytes with proplatelets were counted. On average, 34% ± 1% of vehicle-treated fetal liver–derived megakaryocytes produced proplatelets. Proplatelet formation in vehicle-treated bone marrow–derived megakaryocytes was 50% ± 1%.

Figure 6. Platelet territories and proplatelets fail to form in PSMC1-deficient megakaryocytes. (A) Whereas Psmc1fl/fl Pf4-Cre mice had less cytoplasm compared with the nuclei, those from a Psmc1fl/+ Pf4-Cre mouse had less cytoplasm compared with the multilobed nuclei. Boxed regions are shown at higher magnification below, in which the demarcation membrane exhibited with the multilobed nucleus. (B) Transmission images of megakaryocytes derived from Psmc1fl/fl and Psmc1fl/+ Pf4-Cre mice at P1. Proplatelet formation (arrows) was absent in Psmc1fl/+ Pf4-Cre mice. Scale bars: 2 μm (B); 100 μm (B).

Inhibitors used in these in vitro studies (all diluted in DMSO) included bortezomib (100 nM; Selleck Chem), Y27632 (10 μM; Sigma-Aldrich), fasudil (10 μM; Selleck Chem), C3 transferase (10 μM; Cytoskeleton Inc.), SC-514 (0.5 μM; Calbiochem), MG132 (10 μM; Sigma-Aldrich), and lactacystin (10 μM; Sigma-Aldrich). Inhibitors were administered at different times, as indicated in the figure legends.

Next-generation RNA-Seq

Fetal liver–derived megakaryocytes for RNA-Seq were provided by J. Thon (Harvard Medical School, Boston, Massachusetts, USA). RNA from human CD34-differentiated or fetal liver–derived proplatelet-producing megakaryocytes was isolated and prepped for deep sequencing as previously described (43–45). In brief, RNA was prepared for sequencing according to Illumina’s (DNA Vision) TruSeq kit V2 for poly-A RNA. Libraries were sequenced 36 (human) and 50 (mouse) base pairs on an Illumina sequencer. Reads were aligned using Novoaalign (Novocraft Technologies) software followed by processing, including RPKM assignment, using the USeq analysis package (46). The processed RNA-Seq data and aligned reads were deposited in GEO (accession no. GSE58202; ref. 47).

Protein expression analyses and assessment of RhoA activity

Cell lysates were placed in laemmli buffer, proteins were separated by SDS-page, and stained with a phycoerythrin-conjugated anti-mouse Cytoskeleton Inc.). SC-514 (0.5 μM; Calbiochem), MG132 (10 μM; Sigma-Aldrich), and lactacystin (10 μM; Sigma-Aldrich). Inhibitors were included bortezomib (100 nM; Selleck Chem), Y27632 (10 μM; Sigma-Aldrich), C3 transferase (10 μM; Cytoskeleton Inc.), SC-514 (0.5 μM; Calbiochem), MG132 (10 μM; Sigma-Aldrich), and lactacystin (10 μM; Sigma-Aldrich). Inhibitors were administered at different times, as indicated in the figure legends.

Mouse in vivo studies

In vivo measurements of platelets. In Figure 1A, platelet counts were determined at various time points with a Hemavet 950 (Drew Scientific). For platelet clearance, C57BL/6 mice were injected intravenously (i.v.) on day 0 with anti-GPIBα Dylight 488 (0.1 μg/g body weight; Emfret Analytics) and intraperitoneally (i.p.) with bortezomib (2 mg/kg body weight) or its vehicle (10% DMSO in 0.9% saline). Blood samples (30 μl) were taken daily, diluted in Hanks balanced salt solution, and stained with a phycoerythrin-conjugated anti-mouse CD41 antibody (BD Biosciences), and clearance of Dylight 488–positive platelets was measured as previously described (48).

For estimation of platelet production, C57BL/6 mice were injected i.v. on day 0 with anti-GPIBα antibodies (3 μg/g body weight; Emfret Analytics) to deplete circulating platelets. On day 1,
platelet counts were assessed to confirm depletion; shortly after, mice were treated i.p. with bortezomib or its vehicle as above. Blood samples (2 μl) were taken daily for the remainder of the experiment, and platelet counts were measured by flow cytometry as previously described (13).

Knockout of the proteasome in mouse megakaryocytes and platelets. Megakaryocyte and platelet ablation of proteasome activity was achieved by crossing Psmc1<sup>fl/fl</sup> mice (provided by J. Mayer, Baylor College of Medicine, Houston, Texas, USA) with Pf4-Cre or Pdgf-Cre-ER mice (Jackson Labs), generating Psmc1<sup>fl/wt</sup> and Psmc1<sup>fl/fl</sup> Pf4-Cre mice or Psmc1<sup>fl/wt</sup> and Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER mice. Psmc1<sup>fl/fl</sup> mice were also used as controls in select studies. Knockdown was confirmed in megakaryocytes using an antibody against PSMC1 (Novus Biologicals), and platelet counts were assessed as recently described (49). Tamoxifen (0.25 mg/kg) was administered i.p. to Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER pups on P1, and then mortality was monitored from P2 to P21. For studies in adult Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER mice, tamoxifen was administered 8 weeks after birth. In these mice, fasudil (5 mg/kg) was injected i.p. to Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER mice 4 and 48 hours after tamoxifen administration, and blood was retrieved from tail veins on day 6 after tamoxifen to determine circulating platelet counts. In a subset of mice (n = 2 per treatment group), ex vivo assessment of proplatelet formation was performed. For these studies, mice were euthanized via CO<sub>2</sub> asphyxiation followed by cervical dislocation. Femurs were isolated, and bone marrow cords were flushed with HEPES-tyrodes buffer with 100 U/ml penicillin/streptomycin. Crude bone marrow cords were sliced into multiple sections, and buffer was replaced with HEPES-tyrodes buffer with 5% mouse serum and 100 U/ml penicillin/streptomycin. Bone marrow sections were then incubated at 37°C for 2 hours and stained with

Figure 7. Genetic deletion of Psmc1 in megakaryocytes is associated with increased RhoA protein and activity. (A) Representative Western blot of total RhoA and RhoA-GTP in megakaryocytes derived from Psmc1<sup>fl/wt</sup> and Psmc1<sup>fl/fl</sup> Pf4-Cre mice at P1. Also shown is densitometry quantification relative to Psmc1<sup>fl/wt</sup> control; for RhoA-GTP, megakaryocytes were isolated from 10 P1 mice, lysed, and then the lysates were pooled together for each pulldown experiment (see Methods). Data are mean ± SEM of 3 (total RhoA) and 2 (RhoA-GTP) experiments. *P < 0.05 vs. Psmc1<sup>fl/wt</sup>. (B) Bone marrow–derived megakaryocytes from Psmc1<sup>fl/fl</sup> and Psmc1<sup>fl/fl</sup> Pf4-Cre mice were treated with vehicle or fasudil, and the number of proplatelet-producing megakaryocytes was quantified and expressed relative to Psmc1<sup>fl/wt</sup> controls. Data are mean ± SEM of 3 independent experiments. *P < 0.05 vs. vehicle-treated Psmc1<sup>fl/wt</sup>.

Figure 8. Inhibition of RhoA signaling rescues platelet counts in adult mice in which proteasome activity is conditionally deleted. (A) Tamoxifen was administered to adult Psmc1<sup>fl/wt</sup> and Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER mice, followed by treatment with fasudil or saline control (4 and 48 hours after tamoxifen). Shown are platelet counts at day 6 after tamoxifen administration relative to Psmc1<sup>fl/wt</sup> controls treated with tamoxifen alone. Data are mean ± SEM of 9 experiments performed on independent mice. *P < 0.05 as indicated. No significant difference was observed between groups treated with tamoxifen plus fasudil. (B) Representative images of Dylight 488–positive megakaryocytes present in crude bone marrow isolated from Psmc1<sup>fl/wt</sup> and Psmc1<sup>fl/fl</sup> Pdgf-Cre-ER mice immediately after euthanasia. Bone marrow for these studies was isolated from a subset of the mice in A (n = 2 per treatment group). Scale bars: 100 μm.
anti-GPIbβ Dylight 488. Megakaryocytes were imaged on a Nikon Eclipse TS100 fluorescence microscope and quantified by counting 10 fields (≥20 per well).

Measurement of blood hematocrit
Hematocrit was measured in Psmc1fl/wt and Psmc1fl/fl Pf4-Cre mice at P3. After anesthesia (ketamine-xylazine: 0.2 mg/g body weight), blood was acquired via the retro-orbital venous plexus. Blood was collected into heparinized capillary tubes and spun at 50,000 g for 10 minutes to obtain a hematocrit for each mouse.

Histopathology
Organs from P1 mice were collected and fixed in neutral buffered formalin. Tissues were embedded in paraffin, sectioned at 10 μm, and stained with hematoxylin and eosin (H&E). Slides were then assessed by a hematopathologist.

Electron microscopy
Femurs from mice were collected, and bone marrow was flushed into glutaraldehyde 2.5% in PBS. Fixed samples were kept at 4°C, shipped to the Hospital for Sick Children in Toronto, and further processed and imaged as previously described (50).

Statistics
For multiple-group comparisons, data were subjected to 1-way analysis of variance (ANOVA), and Tukey’s post-hoc test was used to assess statistical significance for the data in Figure 8B. 2-tailed Student’s t-test was used when comparisons were made between 2 groups. Differences in mortality were assessed by χ² test, and observed outcomes were graphed relative to calculated expected outcomes (Figure 5B and Supplemental Figure 13B). When possible, quantifications were done by a blinded observer. P values less than 0.05 were considered statistically significant.

Acknowledgments
We thank Diana Lim for preparation of the figures, critical comments, and consultation regarding responsible and effective display of the images. We also thank Guy Zimmerman for helpful discussions regarding the roles of the proteasome in platelets and megakaryocytes. This work was funded by NIH grants HL066277 and HL112311 (to A.S. Weyrich), HL11231, HL084516, and AR064788 (to D.Y. Li), GM103806 (to J.W. Rowley), and HL68130 (to J.E. Italiano Jr.); by the American Heart Association (13POST13930019 to K.R. Machlus; 11POST1290019 to R.A. Campbell; 0625098Y and 09BG1A 2250381 to H. Schwertz); and by the Canadian Institutes of Health Research (MOP-259952 to W.H.A. Kahr). In addition, H. Schwertz was funded by a Lichtenberg-Professorship from the Volkswagen Foundation.

All data graphed relative to controls (Figures 2–5, 7, and 8 and Supplemental Figures 4, 7, 10, and 13) were generated by comparing the average of the data set in each treated group with that of the control group (as the denominator).

Study approval
The human studies were approved by the University of Utah’s Institutional Review Board (IRB no. 392). All participating subjects provided informed consent. Cord blood from normal full-term deliveries was obtained after informed consent by the mothers (IRB no. 11919). The mouse studies were approved by the University of Utah’s Institutional Animal Care and Review Board (IACUC nos. 12-10002 and 12-1107) or by the Children’s Hospital in Boston (IACUC no. A3431-01).

Further information can be found in the supplemental material and citations therein (51, 52).
