(Submitted for publication October 23, 1958; accepted January 22, 1959)

The mechanism whereby high CO_2 tensions are formed in the urine has been the subject of considerable debate. Pitts and Alexander (1) proposed that the CO_2 tension in alkaline urines is increased as a result of the following sequence: 1) increased delivery of NaHCO₃ to the distal tubule; 2) increased formation of H₂CO₃ as a result of a Na⁺-H⁺ exchange in this segment; 3) delayed dehydration of the H₂CO₃ thus formed. More recently, Kennedy, Eden and Berliner (2) have emphasized the role of nonbicarbonate buffer as the factor responsible for delayed dehydration of H₂CO₃. It is apparent, therefore, that variations in the excretion of buffer as well as bicarbonate might influence the urinary CO₂ tension.

The high CO₂ tensions that follow the administration of Diamox[®] are particularly difficult to explain within this conceptual framework, because Diamox[®] undeniably suppresses overall renal H⁺ secretion. Evidence has recently been presented (3) to support the thesis that the high CO₂ tension in urine during a bicarbonate diuresis induced by Diamox[®] is the consequence, not of the enhanced bicarbonate excretion, but of the buffering action of the inhibitor.

The present studies were designed to examine in man the relationship of buffer and bicarbonate excretion to urine CO_2 tension by observing the pattern of various types of bicarbonate diuresis, including that produced by Diamox[®], with and without the simultaneous infusion of phosphate buffer.

MATERIALS AND METHODS

A total of 27 experiments were performed on normal young adults (medical students, house officers and student nurses) after an overnight fast.

Maximum water diuresis was maintained by the rapid intravenous infusion of either 5 per cent dextrose or 5 per cent fructose in water. The subjects remained recumbent throughout the experiments except for those individuals from whom voided urine specimens were obtained. Urine collection periods of 15 to 20 minutes were employed; the samples were collected under mineral oil by direct voiding in some experiments, by indwelling catheter in most. At the mid-point of each urine collection period blood was drawn into heparinized, oiled syringes from an indwelling needle in either a brachial or femoral artery.

Blood and urine pH were anaerobically determined immediately with a Cambridge pH meter with the electrode assembly housed in an incubator at a constant temperature of 37° C. Plasma and urine CO₂ content were determined by the method of Van Slyke and Neill (4). Bicarbonate concentration and pCO₂ were calculated from the Henderson-Hasselbalch equation. The pK1 of H2CO3 in urine was estimated for each sample according to the formula: $pK_1 = 6.33 - 0.5 \sqrt{B}$, where B represents the total cation concentration of the sample in question (5). It was assumed that the sum [Na⁺]+[K⁺] was equal to at least 95 per cent of [B⁺]. It was found that the arbitrary selection of a pK₁ of 6.10 introduced a variable error of considerable magnitude when calculating pCO₂ in urines of varying pH and bicarbonate concentration. However, using the pK₁ estimated from $6.33 - 0.5 \sqrt{B}$, close agreement was obtained between calculated pCO₂ and tonometrically determined pCO₂. The conventional proportionality constant of 0.0309 was used to convert $[H_2CO_3]$ to pCO₂. For plasma, a pK₁ of 6.10 and a proportionality constant of 0.0301 were used.

Inorganic phosphate in urine was determined by the method of Fiske and Subbarow (6). Titration curves for urines obtained during several of the experiments were determined as follows:

Ten ml. urine was acidified to < pH 2.0 by the addition of 0.1 HCl. Following vigorous stirring for 15 minutes (to dispel generated CO₂), the samples were titrated to pH 6.0 to 6.2 with 0.1 N NaOH. Further titration to pH > 8.0 was performed with 0.01 N NaOH which was

TABLE I The relation of $U-P \ pCO_2$ to bicarbonate excretion during maximal water diversis

* Injection of 250 mg, Diamox[®] intravenously. † The infusion of 7.5 per cent NaHCO₃ was given at the rate of 6 ml. per minute for 40 minutes before urines were collected and continued throughout the experiment at this rate. ‡ Period of hyperventilation. § The infusion of 7.5 per cent NaHCO₃ was given at the rate of 10 ml. per minute for 19 minutes, after which the rate was slowed to 5 ml. rer minute

per minute. || Period of breathing 6 per cent CO₂.

added in small increments with pH determination following each addition.

Eight types of experiments, as charted below, were performed to examine the relationship between bicarbonate excretion and the urine minus plasma (U-P)pCO₂ gradient under conditions of varying plasma acidbase composition and varying bicarbonate and buffer excretion.

Type

Respiratory alkalosis Respiratory alkalosis + Diamox® Respiratory acidosis Respiratory acidosis + Diamox® Metabolic alkalosis Metabolic alkalosis + Diamox® Diamox[®] only Diamox[®] + phosphate infusion Metabolic alkalosis + phosphate infusion

Respiratory alkalosis was induced by voluntary hyperventilation, assisted by a Haliburton IPPB machine, respiratory acidosis by breathing 6 to 6.5 per cent CO₂ in oxygen. Metabolic alkalosis was produced by the intravenous infusion of hypertonic (7.5 per cent) NaHCO₃ at rates of 2 to 6 ml. per minute. The phosphate solutions used were made from Na2HPO4-NaH2PO4 (pH 7.4), diluted to isotonicity and delivered at rates of 4 to 8 ml. per minute. Diamox® was given intravenously as the sodium salt in a single injection of 250 mg.¹

RESULTS

Representative experiments are charted in Table I. Urine pCO₂ was increased following the in-

TABLE II Effects of massive buffer excretion on $U-P pCO_2$ during bicarbonate diuresis

* Injection of 250 mg. Diamox[®] intravenously. † Isotonic sodium phosphate (pH 7.4) was infused at the rate of 8 ml. per minute for 40 minutes before the start of urine collections and was continued at this rate throughout the experiment.

jection of Diamox[®] (C.G.), during NaHCO₈ infusion (J.H.), during NaHCO₈ infusion and Diamox[®] administration (C.D.), during respiratory acidosis with Diamox[®] (N.K.) and during respiratory acidosis alone (J.H.). It was decreased during respiratory alkalosis alone (J.W.) and was not appreciably increased during respiratory alkalosis plus Diamox[®] (J.W.).

These changes in the absolute value of urine pCO₂ cannot automatically be interpreted to indicate increased generation of CO₂ from H₂CO₃ formed within the tubular lumen. Since CO₂ diffuses freely across cell membranes, alterations in plasma pCO₂ will change the pCO₂ in urine without any associated change in intraluminal H₂CO₃ production. To correct for this, pCO₂ has been expressed as the difference between urine and plasma CO_2 tension (7). The ratio U/P pCO₂ (2) has not been used because the same U-Pgradient might result in different ratios. In the last period of Experiment C.G., U-P was 33 mm. and U/P was 1.75. In the last hyperventilation period of J.W., U-P was 26 mm., but a higher U/P ratio of 2.37 was observed.

It is clear from Table I that appreciable bicarbonate diuresis, no matter how induced, was invariably associated with a definite increase in U-Pgradient. The urine concentration of phosphate was exceedingly low throughout the studies and did not increase appreciably during the experiments in which phosphate was not infused.

To determine whether enhanced excretion of buffers other than phosphate might account for the high U-P gradients during NaHCO₃ diuresis, titration curves were determined from urines obtained following Diamox[®] administration (Figure 1) and NaHCO₃ infusion (Figure 2). Despite the fact that a very dilute solution of NaOH was used to titrate the urines, no increases in buffer concentration between control and experimental samples could be detected. Nevertheless, marked increases in U-P pCO₂ occurred. Similar curves were obtained in all experiments where bicarbonate diuresis was produced without phosphate loads.

That great increases in buffer excretion do, in fact, enhance U-P is seen in the representative experiments listed in Table II, where phosphate excretion was increased 20-fold by a phosphate infusion administered during a Diamox[®] induced diuresis. A similar effect of phosphate was found in other studies where NaHCO₃ and phosphate were infused.

Figure 3 illustrates the relation between bicarbonate excretion and U-P pCO₂ for all studies. Under the conditions of these experiments, where maximal water diuresis was maintained, a mean gradient of about 30 mm. Hg was obtained at bicarbonate excretion of approximately 300 μ Eq. per minute, irrespective of the manner in which bicarbonate diuresis was produced. Increasing bicarbonate excretion beyond this point did not increase U-P.

DISCUSSION

An increase in the CO₂ tension of the urine may result from several different processes. First, ele-

FIG. 3. RELATIONSHIP BETWEEN HCO₂⁻ EXCRETION AND URINE MINUS PLASMA CO₂ GRADIENT DURING MAXIMAL WATER DIURESIS

vations of plasma pCO₂ during respiratory acidosis would increase urinary CO₂ tension because of the rapid diffusion of CO₂ between renal blood and tubular urine. Second, the mixture in the bladder of urines of alkaline and acid pH, such as occurs during prolonged urine collection periods when plasma acid-base composition is changing, would readily generate high CO₂ tensions. Third, H,CO₃ might be generated in the collecting ducts as a result of the admixture of acid and alkaline urines originating in heterogeneous nephrons (7). Finally, the secretion of H⁺ by distal tubular cells into luminal fluid containing HCO3⁻ would also result in the formation of H₂CO₃ (1). It should be emphasized that, in order for these last two processes to elevate the U-P gradient, it is necessary that the dehydration of H₂CO₃ be delayed. The obliteration of U-P gradients in alkaline urines following the injection of carbonic anhydrase in amounts sufficient to cause its excretion into the urine (8) strongly supports the central role attributed to delayed dehydration, although it does not establish which of the last two processes is responsible for the formation of H_2CO_3 .

The effects of changes in plasma CO_2 tension are obviated by employing the urine minus plasma (U-P) gradient of pCO₂ rather than the absolute value of pCO₂ as a basis for comparison. The elevation of plasma CO_2 tension during metabolic alkalosis and respiratory acidosis, although raising the CO_2 tension of the urine, would have no effect on the gradient. In the present studies, the short urine collection periods, maximal water diuresis, and constant experimental circumstances all combine to minimize the effects of bladder mixing. The increased U-P gradient observed in all experiments where noteworthy bicarbonate diuresis occurred is, therefore, attributable to events within the kidney.

Kennedy, Orloff and Berliner (7) have proposed that acid and alkaline urines delivered from heterogeneous nephrons are mixed in the collecting duct system, thereby forming H_2CO_3 and hence resulting in a high U-P gradient. In addition to the admixture of acid and alkaline urines, the mixing hypothesis requires, as Kennedy and co-workers point out, that the acid urine involved contain some buffer in order to generate increased urinary CO_2 tension. Inasmuch as the urines obtained in the present studies contained so little buffer, it seems unlikely, although not impossible, that admixture of heterogeneous urines could account for the observed gradients.

Under the conditions of the studies, the high U-P gradients are most reasonably attributed to accelerated delivery of NaHCO₃ to the distal tubule, where the reabsorption of Na⁺ in exchange for H⁺ generated large amounts of H₂CO₃. The dehydration of H₂CO₃ thus formed was delayed, owing to the absence of carbonic anhydrase from tubular urine. Complete dehydration of H₂CO₃, therefore, occurs lower in the urinary tract where unfavorable volume-surface relationships, or less permeable epithelium, serves to perpetuate the gradient.

While accepting the thesis that delayed dehydration of H_2CO_3 is responsible for the high U-P gradients in alkaline urines, Kennedy, Eden and Berliner (2) have presented evidence from *in* vitro studies to show that the dehydration of H_2CO_3 is immeasurably rapid in the absence of nonbicarbonate buffer. They therefore propose that in order for dehydration of H_2CO_3 to be delayed, buffer must be present in the tubular urine. It follows from this that in alkaline urines, the U-P gradient might rise as a result of increased buffer excretion independently of changes in the magnitude of bicarbonate diuresis.

In the present study increased U-P gradients following NaHCO₃ infusions were not accompanied by changes in buffer excretion. Moreover, owing to the fasting state and the maximal water diuresis, the concentration of urinary buffer was exceedingly low. It appears, therefore, that very small amounts of buffer will delay the dehydration of H_2CO_3 sufficiently to generate high U-P gradients. The fact that massive phosphate excretion resulted in a still further increment in U-P gradient suggests that the excretion of buffer, although influencing urine CO_2 tension to some extent, has only a minor effect in the range of buffer excretion ordinarily encountered.

It is especially noteworthy that Diamox[®] increased the U-P gradient to about the same extent as infusions of NaHCO₃ (Figure 3). This is more difficult to explain, inasmuch as the inhibition of renal carbonic anhydrase is associated with diminished overall H⁺ secretion. It has recently been suggested that Diamox® elevates the U-P gradient by its buffering action rather than by its effect on carbonic anhydrase (3). If sufficient Diamox[®] is given, as appears to have been the case in the experiments just cited, its buffering action may be sufficient to produce these effects. This hypothesis, however, could hardly account for the present results. The amounts of Diamox® given were comparatively small (less than 1 mM), phosphate excretion did not appreciably increase, and titration curves disclosed no detectable rise in excretion of total urinary buffer.

Despite the fact that Diamox[®] depresses overall H^+ secretion, it is likely that accelerated production of H_2CO_3 accounts for the high U-P gradients. If the major effect of Diamox[®] were on the proximal tubules with only minor inhibition exerted distally, then the increased amounts of NaHCO₃ which escaped proximal tubular reabsorption would be delivered to the distal tubular exchange site. Here, the Na⁺-H⁺ exchange process would generate large amounts of H₂CO₃ even though the maximum capacity of the distal tubular system to secrete H⁺ might be somewhat depressed. In keeping with this explanation is the recent evidence suggesting that a major site of action of Diamox[®] is the proximal tubule (9).

If buffer excretion does not vary greatly, the magnitude of the U-P gradient appears to be determined by the rate of distal H⁺ secretion relative to the rate of Na⁺ reabsorption, as NaHCO₃ is delivered to the exchange site. From Figure 3, it is apparent that a maximum gradient of approximately 30 mm. Hg is established during water diuresis at a HCO₃⁻ excretion rate of about 300 μ Eq. per minute. This represents the formation of at least 30 × 0.0309 or approximately 1 mM per L. H₂CO₃ in excess of that generated in

urines with no gradient. In addition, of course, some H_2CO_3 doubtless decomposes and is reabsorbed, so that the total distal H⁺ secretion would be much higher.

It is conceivable that Diamox[®] might generate high gradients by inhibiting red cell carbonic anhydrase. Inhibition of CO₂ hydration in the red cell might elevate the CO₂ tension of renal plasma and interstitial fluid. Urine equilibrating with these fluids would therefore have a high CO₂ tension. This elevation of pCO₂ would not be reflected in systemic blood since sufficient time would elapse in the passage of the blood to the heart and lungs to permit the hydration of CO₂ via the uncatalyzed reaction to proceed to equilibrium. Thus, the calculation of the U-P gradient using the CO₂ tension of arterial blood would give a falsely high value. Against such a mechanism, however, is the fact that renal blood flow is very high in relation to the rate of CO₂ production by the kidney, so that inhibition of red cell carbonic anhydrase should have little effect on renal plasma pCO_2 . Moreover, the relation between U-P and HCO3⁻ excretion following the administration of Diamox[®] (Figure 3) is similar to that following NaHCO₈ infusions, suggesting that the generation of H₂CO₃ in the distal tubule is responsible for the U-P gradients in both instances.

SUMMARY

1. The relationship between bicarbonate diuresis and urine minus plasma $(U-P) pCO_2$ gradient was examined in man during maximum H_2O diuresis.

2. It was found that during water diuresis, a maximum U-P pCO₂ of about 30 mm. Hg developed at a HCO₃⁻ excretion rate of about 300 μ Eq. per minute. Buffer excretion was minimal during most of the experiments. The source of the H₂CO₈ (subsequently dehydrated to CO₂ and

 H_2O) is most logically attributed to the secretion of H⁺ into luminal fluid containing HCO₃⁻.

3. Marked increases in urine buffer excretion following phosphate infusions increased U-P gradients moderately, supporting the hypothesis that buffer can influence urinary CO₂ tension by delaying the dehydration of H_2CO_3 .

4. The high U-P gradients generated during Diamox[®] diuresis appear to be the consequence of Na⁺-H⁺ exchange as NaHCO₃ floods the distal tubule, even though total H⁺ secretion at the distal tubular exchange site may be somewhat depressed. This suggests that the principal site of action of Diamox[®] is the proximal tubule.
