Research Article

Fibrinogen degradation products (FDP) D and E are typically present in blood of patients with disseminated intravascular coagulation and related conditions in which granulocyte (PMN) defense against bacterial infection may be compromised. This study was intended to determine whether FDP modify PMN functions critical to their bactericidal activity. Incubation of human PMN and *Escherichia coli* with 50-100 micrograms/ml FDP did not affect phagocytosis, but reduced by greater than 90% the cells' ability to inhibit bacterial colony growth compared with control PMN incubated with albumin or fibrinogen. FDP (10-100 micrograms/ml) inhibited PMN O₂⁻ release and chemotaxis stimulated by FMLP by 17-50% (P less than 0.005) and 41% (P less than 0.01), respectively. Fragment E3, and not fragment D1, was primarily responsible for inhibition of FMLP-induced PMN O₂⁻ release. Phorbol myristate acetate (10 ng/ml), 1-oleoyl-2-acetylglycerol (10⁻⁶ M), AA (4.2 x 10⁻⁵ M), and zymosan-activated serum-stimulated PMN O₂⁻ release were also decreased 37-63% by FDP compared with control protein. There are at least two mechanisms by which FDP may impair PMN responses. With respect to FMLP, FDP (16-100 micrograms/ml) inhibited specific binding to the cell surface over a ligand concentration range of 1.4-85 nM [³H]FMLP. In contrast, FDP did not effect the extent of phorbol ester binding to PMN but blocked activation of protein kinase C. These data suggest that elevated plasma FDP [...]

Abstract

Fibrinogen degradation products (FDP) D and E are typically present in blood of patients with disseminated intravascular coagulation and related conditions in which granulocyte (PMN) defense against bacterial infection may be compromised. This study was intended to determine whether FDP modify PMN functions critical to their bactericidal activity. Incubation of human PMN and *Escherichia coli* with 50–100 $\mu\text{g/ml}$ FDP did not affect phagocytosis, but reduced by > 90% the cells' ability to inhibit bacterial colony growth compared with control PMN incubated with albumin or fibrinogen. FDP (10–100 $\mu\text{g/ml}$) inhibited PMN O_2^- release and chemotaxis stimulated by FMLP by 17–50% ($P < 0.005$) and 41% ($P < 0.01$), respectively. Fragment E_3 , and not fragment D_1 , was primarily responsible for inhibition of FMLP-induced PMN O_2^- release. Phorbol myristate acetate (10 ng/ml), 1-oleoyl-2-acetyl-glycerol (10^{-6} M), AA (4.2×10^{-5} M), and zymosan-activated serum-stimulated PMN O_2^- release were also decreased 37–63% by FDP compared with control protein. There are at least two mechanisms by which FDP may impair PMN responses. With respect to FMLP, FDP (16–100 $\mu\text{g/ml}$) inhibited specific binding to the cell surface over a ligand concentration range of 1.4–85 nM [^3H]FMLP. In contrast, FDP did not effect the extent of phorbol ester binding to PMN but blocked activation of protein kinase C. These data suggest that elevated plasma FDP inhibit several PMN functions critical to the bactericidal role of these inflammatory cells.

Introduction

Fibrinogen (Fbg)¹, fibrin, and degradation products of these plasma proteins (FDP) have important effects on several

aspects of inflammation. Perhaps most thoroughly studied is their role in platelet activation. In many circumstances, occupancy of platelet Fbg receptors with intact Fbg precedes platelet secretion and aggregation which support normal hemostasis (1–3). Elevation in plasma FDP, such as in disseminated intravascular coagulation (DIC) or adult respiratory distress syndrome, may inhibit the interaction between platelet Fbg receptors and Fbg and contribute directly to platelet dysfunction and bleeding diathesis (4–6). Several studies suggest that FDP may also have deleterious effects on other cells involved in acute inflammation. Fragment D, a ~ 100-kD plasmin-generated FDP, induces cytoskeletal alterations and eventual retraction of venous endothelial cells in vitro (7, 8). Fragment E, a ~ 50-kD FDP, competes with Fbg for fibroblast Fbg binding sites and inhibits directed migration of these cells in a Fbg concentration gradient (9, 10). Low molecular weight Fbg degradation products have been shown to decrease lymphocyte blastogenesis (11, 12). With regard to PMN, various low molecular weight (< 20 kD) polypeptides derived from Fbg have been found to induce chemotaxis (13). Possible PMN chemotactic activity of fragment D has also been reported (14, 15). Human fibrinopeptide B has chemotactic activity for PMN in potency equivalent to that of C5a, leukotriene B₄, and FMLP (16). These observations suggest that increases in the plasma concentration of various Fbg fragments modify the inflammatory response by virtue of their effects on multiple cellular components of blood. Because clinical situations in which DIC occurs are commonly associated with severe bacterial infections and neutropenia (17), we initiated studies to define more clearly the effects of FDP and related activated coagulant proteins on PMN functions related to host defense against bacteria.

Methods

Preparation of Fbg and FDP. Lyophilized human Fbg (Imco, Stockholm, Sweden) was dissolved in distilled water and dialyzed against 0.01 M PBS, pH 7, for 18 h at 4°C. Dialyzed Fbg was stored at –20°C until use. To prepare FDP, Fbg was incubated with plasmin (0.0025 mg/ml final concentration) at 37°C for 1–3 h. Proteolysis was stopped by addition of tosyllysyl chloromethyl ketone and phenylalanylarginyl chloromethyl ketone (Sigma Chemical Co., St. Louis, MO), followed by dialysis at 4°C against PBS and sodium azide (18). Mixed D and E fragments were separated from lower molecular weight degradation products by passage of the preparations over a Sephadex G150 column (80 × 2.5 cm). FDP was dialyzed against PBS before use. The presence of D and E fragments was verified by SDS-PAGE run under nonreducing conditions. These preparations displayed characteristic bands of 80–100 (fragments D_{1,2,3}) and 50 kD (fragment E), and minor components between 50 and 100 kD after staining with Coomassie blue (Fig. 1) (18–20). In studies directed at defining the species of FDP that affect FMLP-stimulated PMN O_2^- release, fragments D₁ and E₃ were separated and purified from plasmin-digested Fbg by Pevikon block

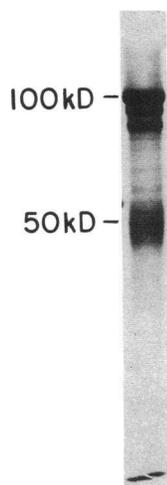

Figure 1. SDS-PAGE of FDP. 20 μg of FDP were run on a 10% SDS-PAGE and stained with Coomassie blue.

electrophoresis as described (21). The homogeneity and lack of cross-contamination between preparations of fragments D_1 and E_3 were confirmed by PAGE. Human plasmin and thrombin were prepared by standard methods (22). Protein concentrations were measured by the method of Lowry et al. (23).

Cells. PMN of healthy adults were prepared from peripheral blood anticoagulated with 1 U/ml heparin by centrifugation through Ficoll-Paque (Pharmacia Fine Chemicals, Piscataway, NJ) followed by sedimentation in 3% dextran in 0.15 M NaCl (24). Contaminating erythrocytes were removed by hypotonic lysis. These preparations contained 95–98% neutrophils and 2–5% eosinophils as assessed by microscopic inspection of Wright's-Giemsa-stained cytocentrifuge preparations. Viability was > 98% as assessed by trypan blue exclusion.

PMN bactericidal activity. To assess bactericidal activity of PMN in the presence of BSA, Fbg, or FDP, a modification of the methods described by Steigbigel et al. (25) and Mandell (26) was used. *Escherichia coli* cultured in trypticase soy broth were washed in 0.15 M NaCl then incubated in HBSS and 10% normal human serum at 37°C for 30 min. After washing three times in HBSS, *E. coli* density was assessed by absorbance in a spectrophotometer. *E. coli* (1×10^7) and PMN (5×10^6) were mixed in 0.7 ml HBSS containing 50% vol/vol heat-inactivated FCS/HBSS/gelatin (Difco Laboratories Inc., Detroit, MI). 100 μl of heat-inactivated (56°C for 1 h) normal human serum and 0.1% vol/vol gelatin containing 50–100 $\mu\text{g}/\text{ml}$ BSA, Fbg, or FDP were then added to triplicate tubes. PMN-bacterial mixtures were incubated at 37°C for 15 min with constant rotation. Extracellular organisms were killed by addition of 100 U/ml of penicillin and 100 $\mu\text{g}/\text{ml}$ of streptomycin (Gibco Laboratories, Grand Island, NY) with continued rotation for 2 h. 200- μl aliquots from each tube were then removed, washed in 0.15 M NaCl, PMN sonicated, and diluted 1:1,000 in HBSS. Triplicate 100- μl aliquots of the diluted sonicates were plated on blood agar and bacterial colonies counted after incubation at 37°C for 24 h.

PMN phagocytosis. 0.5 ml blood was placed on a coverslip and allowed to incubate for 90 min at 37°C in a humidified chamber. The formed clot was rinsed off the coverslip with 0.9% NaCl and 10^7 *E. coli* in 0.5 ml NaCl containing either 100 $\mu\text{g}/\text{ml}$ BSA or FDP. Duplicate coverslips were incubated with added bacteria for 10, 20, or 30 min before washing with saline and fixation with 100% methanol. Phagocytosis was quantified in two ways: (a) the proportion of PMN with ingested bacteria was determined by microscopic inspection of Giemsa-stained smears; and (b) the number of ingested bacteria per PMN was calculated from the total number of *E. coli* counted in 100 PMN (27).

Superoxide production. Superoxide production was measured by SOD-inhibitable cytochrome *c* reduction (28). PMN and cytochrome solution (1.2 mg cytochrome *c*/ml HBSS) were added to glass cuvettes with a final concentration of 1×10^6 PMN/ml HBSS. The cells were incubated for 2 min with 10–100 $\mu\text{g}/\text{ml}$ FDP or control BSA

(< 0.005% fatty acids) at 37°C (or other proteins listed in Results). FMLP, phorbol myristate acetate (PMA), AA, 1-oleoyl-2-acetyl-glycerol (OAG) diluted first in DMSO then PBS, zymosan-activated serum (containing C5a; ZAS) (29), or opsonized zymosan (30) (a phagocytic stimulus), were then added. Absorbance at 550 nm of triplicate samples was measured at 1-min intervals unless otherwise indicated. FMLP, OAG, AA, PMA, cytochrome *c*, and BSA were purchased from Sigma Chemical Co. In some experiments, stimuli were added to PMN suspensions 1.5 or 5.5 min after BSA, Fbg, or FDP. Preliminary experiments using acetaldehyde-xanthine oxidase to generate reduced oxygen products (31) indicated that the amount of O_2^- detected by the cytochrome *c* reduction method was similar in buffer containing 100 $\mu\text{g}/\text{ml}$ BSA, Fbg, or FDP.

Chemotaxis. A modification of the chemotaxis under agarose assay (32) was used to assess chemotactic responses of PMN to FMLP in the presence of FDP, Fbg, or BSA. A layer of 0.6% wt/vol agarose was poured into plastic petri dishes and a circular array of wells cut into the gel using a standard template. PMN and either FDP or BSA (100 $\mu\text{g}/\text{ml}$) were placed in a middle well. FMLP (1×10^{-6} M) or HBSS alone was then added to opposite outer wells. After 2 h incubation at 37°C in 5% CO_2 in air, the agar dishes were fixed with methanol and formalin, dried, and stained with Wright's-Giemsa for microscopic inspection. The chemotactic index was calculated by dividing the linear distance of the leading edge of PMN moving from the center well toward the outer well containing FMLP by the linear distance of PMN traveling toward the control well containing buffer alone.

Measurements of FMLP and phorbol ester binding to PMN. In the initial series of experiments PMN binding of FMLP was measured as described previously (33). Briefly, triplicate aliquots of 5×10^6 PMN in 0.5 ml HBSS were preincubated for 2 min with 100 $\mu\text{g}/\text{ml}$ BSA, or FDP at 25°C. 1.7×10^{-9} M [^3H]FMLP (specific activity 48.3 Ci/mmol; New England Nuclear, Boston, MA) with or without 1,000-fold excess unlabeled FMLP was added and incubation continued for 30 min. PMN suspensions were then layered on silicone oil (PC550; Fluka AG, Ronkonkoma, NY) contained in plastic tubes and cell pellets obtained by centrifugation (10,000 g) for 2 min. The bottom of the tube containing the cell pellet was cut off, placed in liquid scintillation counting fluid, and bound counts per minute determined by beta spectrometry. Specific binding of FMLP was calculated by subtraction of counts per minute bound in the presence of excess unlabeled FMLP from counts per minute in the absence of excess FMLP. Additional experiments were performed to examine whether FDP preferentially altered binding to high or low affinity PMN FMLP receptors. Internalization of chemotactic peptide receptors and FDP by PMN was minimized by carrying out 30-min incubations at 4°C in HBSS containing 10 mM sodium azide and 10 mM 2-deoxyglucose (Sigma Chemical Co.) (34). 1.4–85 nM [^3H]FMLP (60.0 Ci/mmol; Amersham Corp., Arlington Heights, IL) was incubated with triplicate samples of 2.5×10^6 PMN in the presence of either 100 $\mu\text{g}/\text{ml}$ BSA or FDP. A 1,000-fold excess of unlabeled FMLP was added to determine nonspecific binding. Based on previous studies (35, 36), a two-site saturable model for FMLP receptors was assumed. Binding data were analyzed using NONLIN, a weighted nonlinear least squares regression computer program (37). To examine the concentration dependence of the possible effect of FDP on PMN FMLP binding, a similar assay was set up with 21 nM [^3H]FMLP as input and FDP concentrations ranging from 16 to 100 $\mu\text{g}/\text{ml}$.

Phorbol ester binding to PMN was quantified by measurements of specific binding of [^3H]phorbol-12,13-dibutyrate (PDBU) (38). PMN (1×10^6) were suspended in 200 μl HBSS at 25°C in plastic microtiter wells containing either 100 $\mu\text{g}/\text{ml}$ BSA or 100 $\mu\text{g}/\text{ml}$ FDP. 2×10^{-7} M [^3H]PDBU (18.9 Ci/mmol; New England Nuclear) in the presence or absence of 5×10^{-5} M unlabeled PMA was added and incubation continued for 20 min at 37°C. PMN in triplicate wells were then harvested on to glass filter paper and specific binding of [^3H]PDBU determined.

Binding of fluid-phase ligands to FDP and BSA. To determine whether FMLP, phorbol esters, or AA bound differentially to FDP vs.

BSA, 1.7×10^{-9} M [^3H]FMLP (48.3 Ci/mmol), 2×10^{-7} M [^3H]PDBU (18.9 Ci/mmol), or 8.2×10^{-7} M [^3H]AA (191 Ci/mmol; Amersham Corp.) was incubated with BSA or FDP (50 $\mu\text{g}/\text{ml}$) in PBS for 1 h at 37°C. The mixtures were then layered on a G-25 Sephadex column preequilibrated with excess BSA and 0.5-ml fractions eluted with PBS. The profile of protein elution was measured with a spectrophotometer (A_{280}) and the pattern of ligand elution determined by beta spectrometry. The patterns of [^3H]ligand coeluting with protein and free ligand were compared for BSA and FDP.

Effect of FDP on PKC activation by phorbol esters. The effect of FDP on PMN PKC activation was compared with that of BSA using the method of TerBush and Holz (39). PMN (10^7) were incubated in HBSS with 10^{-8} M PMA in the presence of either FDP or BSA (100 $\mu\text{g}/\text{ml}$) for 10 min at 37°C. The cells were then washed three times in HBSS and resuspended in 0.4 ml cold (4°C) homogenizing buffer consisting of 139 mM potassium glutamate, 20 mM Pipes, pH 6.6, 5 mM EGTA, 5 mg/ml BSA, and 50 $\mu\text{g}/\text{ml}$ leupeptin (KGEP) as described (40). The suspensions were sonicated twice (setting of 7 for 10 s; Kontes Co., Vineland, NJ) and subjected to centrifugation at 148,000 g for 10 min. The supernatant (containing cytosol) was removed. The pellet (containing membranes) was washed twice in cold KGEP, resuspended in KGEP with trituration, and Triton X-100 added to both pellet and supernatant to a final concentration of 0.1%. 20 μl of each fraction was then added to a protein kinase C (PKC) assay solution containing 42 mM potassium glutamate, 20 mM Pipes (pH 6.6), 10 mM MgCl_2 , 10 mM DTT, 0.01% Triton X-100, 50 μg histone/ml, 0.8 mg BSA/ml, ± 0.8 mM CaCl_2 , ± 167 μg phosphatidylserine/ml, ± 26.7 μg 1,2-diolein/ml per tube. The reaction was started by addition of 30 mM [^{32}P]ATP (100,000 cpm; sp act, 23.8 Ci/mmol; New England Nuclear) and incubation carried out for 10 min at 28°C. The reaction was stopped by addition of 5% TCA, 0.25% sodium tungstate, 15 mM NaH_2PO_4 , and 2 mM ATP. After addition of BSA and washing, the radioactivity in each of the precipitates from the PMN pellet fraction (membranes) and supernatant fraction (cytosol) was determined. PKC activity is defined as the difference between activity in Ca^{2+} and phosphatidylserine/diglyceride buffer vs. buffer without Ca^{2+} and phosphatidylserine/diglyceride. Results are expressed as picomoles phosphate incorporated/10 min per 10^7 PMN. Comparisons of PKC activities in cytosolic (supernatant) and membrane (pellet) fractions were performed as a measure of translocation of PKC from the cytosol to membrane that occurs concomitantly with phorbol ester-induced cellular activation (41).

Results

PMN bactericidal and phagocytic activity in the presence of FDP. PMN incubated with 100 $\mu\text{g}/\text{ml}$ FDP had significantly less ($\alpha < 0.05$, Wilcoxon-rank sum test) bactericidal activity for ingested *E. coli* compared with autologous cells mixed with an equivalent protein concentration of Fbg or BSA. Colony counts resulting from PMN preincubated with BSA ranged from 1 to 10 vs. 35 to 177 for those with FDP. FDP at a concentration of 50 $\mu\text{g}/\text{ml}$ also significantly reduced the ability of PMN to kill *E. coli* (Table I). BSA, Fbg, or FDP had no effect on bacterial colony counts when PMN were omitted (data not shown). In contrast to the inhibitory effects of FDP on PMN bacterial killing, phagocytosis of *E. coli* was unaffected. In the presence of 100 $\mu\text{g}/\text{ml}$ BSA, 7, 45, and 85% of PMN contained ingested bacteria after 10, 20, and 30 min, respectively. The respective values for PMN coincubated with 100 $\mu\text{g}/\text{ml}$ FDP were 6, 44, and 90% (duplicate samples from a single donor). There was also no difference in the number of bacteria per PMN. At 10, 20, and 30 min of incubation the respective values for PMN/BSA mixtures were 0.08, 2.85, and 16.10 bacteria/cell vs. 0.06, 3.30, and 17.65 bacteria/cell for PMN/FDP mixtures.

Table I. Capacity of PMN To Exert Bactericidal Activity against *E. coli* in the Presence of BSA, Fbg, or FDP

| Cell donor | Number of bacterial colonies* (PMN coincubated with the following proteins) | | |
|------------|---|-----|-----|
| | BSA | Fbg | FDP |
| 1 | 2 [‡] | 4 | 177 |
| 2 | 1 | 2 | 45 |
| 3 | 10 | ND | 45 |
| 4 | 3 | ND | 35 |
| 5 | 3 | ND | 30 |

* PMN (5×10^6) and *E. coli* ($\sim 10^7$) were incubated in presence of BSA or FDP (100 $\mu\text{g}/\text{ml}$ for cell donors 1–4 and 50 $\mu\text{g}/\text{ml}$ for donor 5) for 15 min, noningested bacteria were killed by addition of penicillin and streptomycin, and incubation was continued for 2 h at 37°C (25, 26). PMN were then sonicated, aliquots plated on blood agar, and bacterial colonies counted after incubation for 24 h at 37°C.

ND, not done.

Effects of plasma coagulant proteins on FMLP-stimulated PMN O_2^- release. Incubation of PMN with FDP (10–100 $\mu\text{g}/\text{ml}$), Fbg (10–200 $\mu\text{g}/\text{ml}$), plasmin (10 $\mu\text{g}/\text{ml}$), thrombin (1 or 10 U/ml), or BSA (100 $\mu\text{g}/\text{ml}$) for 10 min did not result in detectable O_2^- release. Cell viability as assessed by trypan blue exclusion was $> 98\%$ before and after addition of each of the proteins.

When 5×10^{-7} M FMLP was added to PMN suspended in 100 $\mu\text{g}/\text{ml}$ BSA, 2.5–22.5 nmol $\text{O}_2^-/10$ min was released. Substitution of BSA with an equivalent concentration of FDP resulted in a 49–57% reduction of FMLP-stimulated O_2^- accumulation using PMN of six donors ($P < 0.005$ by paired *t* test, Fig. 2). The ranges for triplicate determinations represented by the mean values in this figure and Fig. 3 vary $< 10\%$ from the mean in every case. For example, the mean of 22.5 nmol $\text{O}_2^-/10$ min (the highest point under CONT. in Fig. 2) was calculated from values ranging from 21 to 23 nmol $\text{O}_2^-/10$ min. In contrast to FDP, Fbg (100 $\mu\text{g}/\text{ml}$), thrombin (1 or 50 U/ml), or plasmin (10 $\mu\text{g}/\text{ml}$) did not affect the amount of FMLP-induced PMN O_2^- release compared with cells incubated with 100 $\mu\text{g}/\text{ml}$ BSA (range of 5 to 15 nmol $\text{O}_2^-/10$ min in five experiments comparing coagulant proteins with BSA). The inhibitory effect of FDP on FMLP-induced O_2^- release was not observed when FDP were removed before addition of the activating ligand. PMN were preincubated with 100 $\mu\text{g}/\text{ml}$ FDP for 10 min at 37°C, washed three times in HBSS, and 5×10^{-7} M FMLP added. A total of 9.8, 11.6, and 13.0 nmol $\text{O}_2^-/10$ min

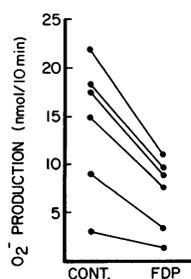

Figure 2. PMN O_2^- release induced by FMLP in the presence of 100 $\mu\text{g}/\text{ml}$ BSA (CONT.) or 100 $\mu\text{g}/\text{ml}$ FDP. FMLP (5×10^{-7} M) was added to triplicate PMN samples for each cell donor 2 min after BSA or FDP. $P < 0.005$ for CONT. vs. FDP.

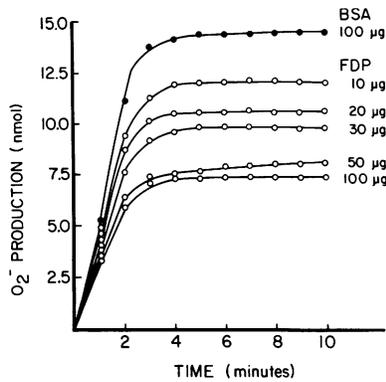

Figure 3. Kinetics of FMLP-induced PMN O_2^- release in the presence of 10–100 $\mu\text{g/ml}$ FDP (○) or 100 $\mu\text{g/ml}$ BSA (●). FMLP (5×10^{-7} M) was added to PMN 2 min after BSA or FDP. Results at each time point represent the mean of duplicate cell suspensions.

per 10^6 cells (mean \pm SE of 11.4 ± 0.9) was released using PMN of three donors. Substitution of BSA for FDP in these experiments resulted in release of 10.2, 11.1, and 12.3 nmol O_2^- , respectively (mean \pm SE of 11.2 ± 0.6 , $P > 0.05$ vs. FDP).

Results of studies examining the effects of various concentrations of FDP on FMLP-induced PMN O_2^- release are presented in Fig. 3. Compared with control PMN incubated with 100 μg BSA/ml, concentrations of 10, 20, and 50 μg FDP/ml inhibited PMN O_2^- released over 10 min by 17, 35, and 50%, respectively. The maximal rate of O_2^- release (calculated from the steepest portion of the curve representing change in absorbance vs. time) also decreased progressively in the presence of increasing concentrations of FDP (15, 23, 32, 42, and 48% reductions with 10, 20, 30, 50, and 100 $\mu\text{g/ml}$ FDP). Further inhibition was not observed when 200 $\mu\text{g/ml}$ FDP was added (data not shown). Similar results were obtained using cells from two other donors. No difference in FMLP-induced PMN O_2^- release was observed in the presence of equivalent concentrations of Fbg or BSA.

To determine whether the inhibitory effect of FDP could be reversed by increasing the amount of stimulating ligand, PMN were preincubated for 2 min with 100 μg BSA/ml (control) or 100 μg FDP/ml and increasing amounts of FMLP added. When 1×10^{-7} M FMLP was added, 50% inhibition of PMN O_2^- release was produced by FDP (11 ± 2 nmol/10 min for FDP vs. 22 ± 3 nmol/10 min in BSA controls, mean \pm SE of experiments using PMN of three individuals). A similar degree of FDP-induced inhibition (62%) occurred when the FMLP concentration was increased to 5×10^{-7} M (16 nmol O_2^- /10 min with FDP vs. 42 nmol/10 min with BSA). Less inhibition was observed when the concentration of FMLP was increased to 1×10^{-6} M. In two experiments control PMN released 58 ± 4 and 60 ± 2 nmol O_2^- /10 min vs. 51 ± 1 and 56 ± 4 nmol/10 min in the presence of FDP (25 and 16% inhibition, respectively).

As a first step in defining the specific proteins in FDP responsible for suppression of PMN responses, PMN were preincubated with purified fragments D_1 or E_3 2 min before addition of 5×10^{-7} M FMLP. Release of O_2^- from PMN preincubated with 10 $\mu\text{g/ml}$ BSA (controls) was 20.0 ± 1.0 nmol/10 min. In the presence of 10 $\mu\text{g/ml}$ fragment D_1 or E_3 these values were, respectively, 20.0 ± 1.5 and 14.1 ± 2.0 nmol O_2^- /10 min (mean \pm SD for triplicate determinations of PMN of one donor; $P < 0.05$ for fragment E_3 vs. controls). Using PMN of a second donor preincubated with 50 $\mu\text{g/ml}$ BSA or fragment D_1 , O_2^- release over 10 min was, respectively, 16.1 ± 1.0 and 16.0 ± 2.0 nmol. In contrast, fragment E_3 at a

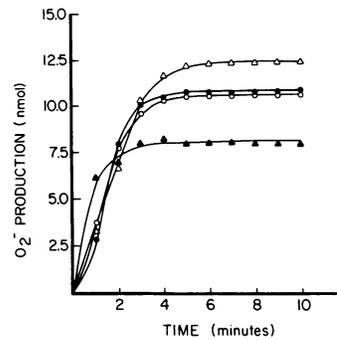

Figure 4. Effect of time of addition of FDP or BSA on kinetics of FMLP-stimulated PMN O_2^- release. 5×10^{-7} M FMLP was added to PMN at time 0. BSA (100 $\mu\text{g/ml}$) was added 1.5 (●) or 5.5 min (○) later. In parallel studies, FDP (100 $\mu\text{g/ml}$) was added 1.5 (▲) or 5.5 min (△) later. Results represent the mean of triplicate determinations at each time point.

concentration of 50 $\mu\text{g/ml}$ suppressed O_2^- release from PMN of a third donor by 21% (29.1 ± 3.0 in the presence of 50 $\mu\text{g/ml}$ BSA vs. 22.0 ± 3.0 nmol/10 min, $P < 0.05$).

Capacity of FDP to reverse FMLP-induced PMN O_2^- release. To ascertain whether FDP could abrogate O_2^- production from PMN previously exposed to FMLP, 100 $\mu\text{g/ml}$ FDP or control BSA was added to cells 1.5 or 5.5 min after 5×10^{-7} M FMLP. Addition of BSA 1.5 (Fig. 4, closed circles) or 5.5 min (open circles) after FMLP did not have a differential effect on the rate or accumulation of O_2^- generated by PMN (10.5 ± 1.0 nmol O_2^- over 10 min, mean \pm SD of triplicate determinations). In contrast, addition of FDP 1.5 min after FMLP (closed triangles) resulted in an immediate decrease in the rate and accumulation of O_2^- compared with addition at 5.5 min (open triangles) (7.5 ± 0.5 nmol/10 min vs. 12.5 ± 1.5 nmol/10 min).

Binding of fluid-phase FMLP by FDP. Results reported thus far are consistent with a mechanism whereby FDP bind fluid-phase FMLP more effectively than BSA, thereby preventing interaction of the stimulus with its cellular target. To examine this possibility, equivalent concentrations (50 $\mu\text{g/ml}$) of FDP or BSA were incubated with radiolabeled FMLP and the proportions of protein-bound vs. free ligand compared. 100% of added radiolabel coeluted with free ligand for mixtures of FMLP/BSA and FMLP/FDP. FMLP thus did not appear to bind to either protein.

Effect of FDP on PMN binding of FMLP. Because our previous experiments demonstrated that the effects of FDP on FMLP-induced PMN O_2^- release occurred when the proteins were added subsequent to ligand (Fig. 4) and were not secondary to removal of fluid-phase FMLP by protein binding, we next evaluated the possibility that FDP interferes with interaction of FMLP with the PMN surface. In experiments using cells of four donors, FMLP binding was $72 \pm 12\%$ (mean \pm SE) lower in the presence of 100 $\mu\text{g/ml}$ FDP compared with an equivalent concentration of BSA (1.7 nM input of [^3H]FMLP) (Table II). There were no differences in the effects of Fbg and BSA on PMN binding of FMLP (Table II). To define in more detail the possible interaction of FDP with FMLP receptors, additional experiments were performed in conditions limiting PMN internalization of FMLP and coagulant proteins and over a broad concentration range of radiolabeled ligand (1.3–85 nM [^3H]FMLP). In the presence of 100 $\mu\text{g/ml}$ BSA (control protein), PMN were calculated to have high affinity FMLP receptors with $K_d = 2.8 \times 10^{-9}$ M and low affinity receptors with $K_d = 1.5 \times 10^{-7}$ M (curve generated from triplicate determinations of six points) (Fig. 5). Parallel studies con-

* [³H]FMLP (1.7 × 10⁻⁹ M) was incubated in the presence or absence of 1,000-fold excess unlabeled FMLP with BSA, Fbg, or FDP to measure specific binding (32). Results represent the mean of triplicate determinations for each cell donor.

[‡] Percent reduction compared with BSA.

[§] [³H]PDBU (2 × 10⁻⁷ M) was incubated in the presence or absence of 250-fold excess unlabeled PMA with BSA or FDP (100 µg/ml) to measure specific binding (38). Results represent the mean of duplicate determinations for each cell donor.

ND, not done.

ducted with 100 µg/ml FDP showed that FMLP binding was reduced > 90% in both the steep and flat portions of the curve generated by the Scatchard plot (Fig. 5). Additional binding studies showed that lower concentrations of FDP also inhibited PMN-FMLP interaction. When the total protein concentration was kept constant at 100 µg/ml, increasing the proportion of FDP:BSA from 16 to 25% resulted in respective reductions of specific FMLP binding of 44 and 80% compared with samples containing BSA alone (mean of triplicate samples at each point, Fig. 6). Greater reduction in specific radiolabeled ligand binding was not demonstrable when the FDP concentration was increased to 50 or 100 µg/ml (85% decreases in binding compared with PMN coincubated with 100 µg/ml BSA and no FDP) (Fig. 6). The input of [³H]FMLP in these experiments was 21 nM.

FDP and other procoagulant protein effects on FMLP-stimulated PMN chemotaxis. FMLP-stimulated chemotaxis was used as an additional functional assay, independent of oxidative metabolism, to confirm that FDP interfered with ligand binding to PMN. In experiments using cells from four donors,

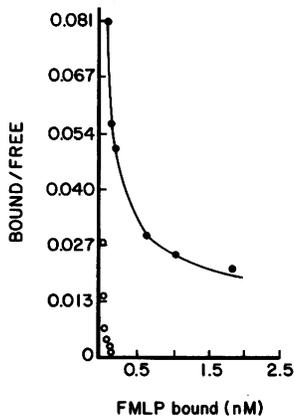

Figure 5. Scatchard plot of FMLP binding to PMN in the presence of 100 mg/ml BSA or FDP. Specific binding FMLP was measured in conditions that minimize internalization of ligand as previously described (34, 35). Each point represents the mean of triplicate determinations. Curves were generated according to NONLIN computer program with a two-site model of FMLP binding assumed (36). Closed circles represent FMLP binding in the presence of 100 mg/ml BSA. Open circles represent binding in the presence of 100 mg/ml FDP.

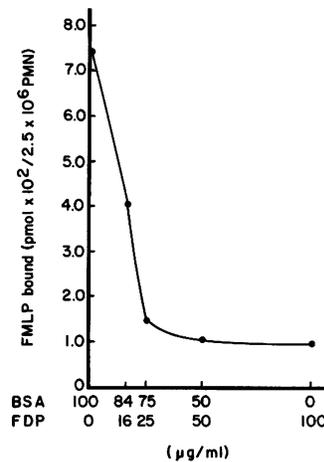

Figure 6. Concentration dependence of FDP inhibition of FMLP binding to PMN. Specific binding of FMLP was measured as described with 21 nM [³H]FMLP input (35). The total protein concentration was constant at 100 µg/ml and the proportion of BSA:FDP varied as indicated on the abscissa. Each point represents the mean of triplicate determinations.

FDP reduced directed migration of PMN by 32–48% compared with BSA. A chemotactic index of 3.4 ± 0.4 (mean ± SE) was obtained for control PMN incubated with BSA vs. 2.0 ± 0.3 for those with FDP (*P* < 0.01) (Table III). The chemotactic indices of PMN incubated with Fbg (100 µg/ml), thrombin (50 U/ml), or plasmin (10 µg/ml) did not differ significantly from controls (data not shown for latter two proteins).

FDP modification of PMN O₂ release induced by additional nonphagocytic and phagocytic stimuli. To examine whether the inhibitory effect of FDP occurred under circumstances involving other nonphagocytic stimuli, studies were conducted with PMA, OAG, AA, and ZAS. PMA and OAG may stimulate the respiratory burst primarily through direct activation and translocation of PKC (41), while the mechanism by which AA induces PMN O₂ release is not well established (42). ZAS containing C5a presumably stimulates PMN respiratory burst activity by a pathway similar to that for other ligands having surface PMN receptors (e.g., FMLP). When 10 ng/ml PMA was added to PMN, O₂ release was 20–74% lower in the presence of 100 µg/ml FDP vs. an equal concentration of BSA (*P* < 0.001, Table IV). Unlike the situation with FMLP, however, addition of FDP 1.5 min after PMA did not inhibit PMN O₂ release (data not shown). Stimulation of

Table III. FMLP-induced PMN Chemotaxis in the Presence of BSA, Fbg, or FDP

| PMN donor | Chemotactic index (Protein [100 µg/ml] added to PMN) | | |

* Results represent the mean of triplicate determinations using a chemotaxis in agarose technique (32).

[‡] This value is the percent inhibition compared with PMN incubated with BSA.

[§] The mean value for PMN preparations incubated with FDP was significantly less compared with controls (BSA) with *P* < 0.01. ND, not done.

Table IV. Effect of FDP on PMA-stimulated PMN O₂ Release

| Experiment | Maximal rate of O ₂ release | | |
|------------|--|-----------------|---------------------|
| | BSA (100 µg/ml) | FDP (100 µg/ml) | % Inhibition by FDP |
| | <i>nmol/min</i> | | |
| 1 | 6.8* | 1.8 | 74 |
| 2 | 3.5 | 2.2 | 37 |
| 3 | 8.8 | 5.6 | 36 |
| 4 | 8.7 | 7.0 | 20 |
| 5 | 8.1 | 4.9 | 39 |
| 6 | 7.0 | 4.8 | 31 |

PMN were incubated with 100 µg/ml BSA or FDP at 37°C and 10 ng/ml PMA added 2 min later. Maximal rates were calculated from the steepest portion of curve generated by absorbance readings taken at 1-min intervals (28).

* Results represent the mean of triplicate determinations.

PMN O₂ release induced by OAG was also inhibited by FDP. PMN preincubated with 100 µg BSA/ml for 2 min followed by addition of 10⁻⁶ M OAG released 8.9±0.4 nmol O₂/20 min (mean±SD of triplicate determinations), whereas those preincubated with 100 µg FDP/ml released 3.3±0.6 nmol (*P* < 0.01). AA (4.2 × 10⁻⁵ M)-induced O₂ release was also reduced by FDP. PMN of two donors stimulated with AA released 20.0 and 19.0 nmol O₂/10 min per 10⁶ cells in the presence of 100 µg/ml BSA vs. 8.4 and 8.0 nmol/10 min, respectively, when an equivalent concentration of FDP was included. Addition of FDP to PMN 1.5 min after AA did not affect O₂ release, as reported for PMA. Addition of 20 µl ZAS to 10⁶ PMN suspended in 1 ml buffer containing 100 µg/ml Fbg resulted in generation of 1.3±0.4 nmol O₂ over a 10-min period (triplicate samples). When the same individual's PMN were stimulated simultaneously with ZAS in the presence of 10, 50, or 100 µg/ml FDP (the remaining protein in the former two samples consisted of Fbg), the amount of O₂ released decreased to 1.1±0.1, 1.0±0.2, and 0.9±0.1 nmol O₂.

In contrast to the inhibitory effects of FDP on PMN O₂ release induced by these nonphagocytic stimuli, O₂ release induced by phagocytosis of opsonized zymosan was not altered. 50 µl opsonized zymosan was added to PMN coincubated with either 100 µg/ml BSA or FDP. The mean amounts of O₂ released over a 30-min period in the presence of BSA vs. FDP were, respectively, 14.6 vs. 15.8, 2.6 vs. 5.3, and 21.9 vs. 17.4 nmol (cells of three individuals, *P* > 0.05).

Effect of FDP on AA and phorbol ester binding to PMN. We determined first whether FDP bound fluid-phase phorbol ester or AA to a greater extent than BSA. In the case of [³H]PDBU, 100% of radiolabel coeluted with free ligand after preincubation with BSA or FDP, as described for FMLP. In contrast, AA bound to both BSA and FDP. Coincubation of [³H]AA with BSA for 1 h resulted in 55.9% of radiolabel being protein bound and 44.1% unbound. When FDP was substituted, 2.2% of radiolabel bound to protein vs. 97.8% unbound. These data indicate that BSA binds AA to a greater extent than FDP in our assay conditions. To ascertain whether FDP also reduced PMN binding of phorbol esters as reported for FMLP, specific binding of [³H]PDBU was measured in the presence of BSA or FDP (100 µg/ml). Similar amounts of PDBU were specifically

Table V. Effect of FDP on Activation and Translocation of PMN PKC

| Donor | Protein | PKC activity* | |
|-------|---------|---|---------------------------|
| | | Unstimulated | PMA stimulated |
| | | <i>pmol P/10 min per 10⁷ PMN</i> | |
| F.H. | BSA | 410±31 [‡] (75) [§] | 581±19 (25) |
| | FDP | 500±27 (65) | 490±20 (59) |
| J.K. | BSA | 498±53 (67) | 613±28 [§] (35) |
| | FDP | 491±29 (72) | 486±25 (63) |

* PMN were incubated with 100 µg/ml BSA or FDP and PKC activity was measured after exposure to buffer alone (unstimulated) or 10⁻⁸ PMA (39, 40).

[‡] This value represents the mean of triplicate determinations.

[§] The number within the parentheses represents the percent PKC activity in the soluble (cytoplasmic) fraction of PMN sonicates subjected to centrifugation at 148,000 *g* for 10 min.

^{||} *P* < 0.05 compared with unstimulated PMN.

bound by PMN when the assay was performed in the presence of BSA or FDP (Table II).

PKC activation. FDP completely abrogated PKC activation by PMA in intact PMN. When 10⁻⁸ M PMA was added to PMN coincubated with 100 µg/ml FDP, there was no change in total PKC activity or the proportion in soluble fractions of PMN sonicates (65 and 72% for unstimulated cells). In contrast, when PMN were coincubated with 100 µg/ml BSA, PMA caused a 23–41% increase in total PKC activity (*P* < 0.05) and one-third to one-half reduction in the proportion in soluble fractions (Table V). Cells not exposed to protein or PMA had values that were identical to those incubated with BSA (e.g., 400±35 pmol P/10 min per 10⁷ PMN with no protein or PMA vs. 380±40 pmol P/10 min per 10⁷ PMN with 100 µg/ml BSA; triplicate samples for each with cells of one donor).

Discussion

Fbg and several proteolytic fragments of this plasma protein have important effects on circulating PMN. Low molecular weight (< 20 kD) fragments produced by extensive plasmin digestion are chemotactic for rabbit PMN in vitro and induce egress from the vascular space in vivo (43, 44). Fibrinopeptide B, a thrombin-derived cleavage product of Fbg BB chains, is also chemotactic but does not stimulate degranulation or respiratory burst activity (16). The possible alterations in PMN function mediated by FDP D and E, the major FDP elevated in plasma of persons with DIC and predisposing conditions such as adult respiratory distress syndrome (45–47) have, however, not been studied. The current results indicate that FDP D and E at concentrations similar to those observed in DIC significantly impair the capacity of PMN to kill *E. coli* in vitro. This defect in bactericidal function is apparently related to alterations in intraphagolysosomal function since bacterial phagocytosis and extracellular release of O₂ induced by phagocytic stimulation (opsonized zymosan) were unaffected by FDP. To define the possible basis of the FDP inhibitory effect on PMN bactericidal function, a series of studies using ligands that elicit relevant PMN responses by initially occupying sur-

face-exposed receptors (i.e., FMLP or C5a) or by directly binding and activating PKC (PMA and possibly AA) were conducted.

Several aspects of the PMN response to FMLP are inhibited by FDP but unaffected by thrombin, plasmin, or Fbg. Superoxide production decreases in a dose-dependent manner upon addition of 10–100 $\mu\text{g/ml}$ of fragments D and E. Comparison of the capacities of purified preparations of fragments D₁ and E₃ to affect FMLP-stimulated PMN O₂⁻ production suggests that the latter fraction is responsible for the inhibitory effect of FDP. These experiments have not excluded the possibility that higher concentrations of fragment D₁ than those used here (50 $\mu\text{g/ml}$) might also be inhibitory. As a first step in dissecting the possible mechanism of FDP inhibition of FMLP-stimulated PMN O₂⁻ release, we examined the reversibility of the effect. Whereas preincubation of cells with FDP followed by washing failed to alter FMLP-induced O₂⁻ release, addition of FDP 1.5 min after FMLP resulted in immediate curtailment of oxyradical accumulation. Since continual occupancy of FMLP receptors is required for optimal stimulation of PMN O₂⁻ release (48, 49), these results suggest that FDP disrupts the interaction of FMLP with its corresponding cellular receptors. The ability of FDP to inhibit FMLP-induced PMN chemotaxis without binding directly to fluid-phase ligand is also consistent with a process involving impairment of cellular receptor-FMLP interaction. To examine this event directly, specific binding of [³H]FMLP to PMN was measured. FDP inhibited FMLP binding (1.7 nM input) by 50–98%. The inhibitory effect occurred at FDP concentrations as low as 16 $\mu\text{g/ml}$ and was maximal at $\geq 25 \mu\text{g/ml}$. Chemotactic binding studies performed over a broad concentration range of [³H]FMLP in conditions that minimize receptor internalization showed that FDP reduced FMLP binding at all levels of [³H]-ligand input. These results suggest that FDP do not interfere preferentially with FMLP interaction with high or low affinity PMN chemotactic peptide receptors. However, more detailed studies using multiple concentrations of FMLP input are required to confirm this. It is also not possible on the basis of these data to distinguish among the possible mechanisms by which FDP interfere with FMLP binding to PMN, e.g., occupancy of the FMLP binding site(s), steric hindrance, alterations in surface receptor mobility, and/or stabilization of the receptor-ligand complex (50).

The effects of Fbg fragments D and E on PMN oxidative metabolism are not limited to FMLP stimulation. Production of O₂⁻ induced by PMA, AA, and OAG are also significantly reduced by FDP. The pathways by which these stimuli induce PMN O₂⁻ release are the subject of a great deal of study and have not been completely elucidated. These molecules are lipophilic and rapidly interact with the PMN plasma membrane. PMA and probably OAG bind directly to PKC (41, 51, 52) and induce translocation of the enzyme from the cytosol to plasma membrane (51). This process is concurrent with activation of the enzyme(s) involved in the initial one electron reduction of O₂ (41). Although the mechanisms by which AA activates the respiratory burst have not been well defined, this lipid may alter surface membrane fluidity (53, 54), directly activate PKC in some circumstances (55, 56), and is a required cofactor for NADPH oxidase activity prepared from broken resting PMN (57, 58). The current studies indicate that FDP inhibition of respiratory burst activity induced by these stimuli is not attributable to protein binding of fluid-phase ligands or

interference with phorbol ester binding to PMN. Rather, our observations are consistent with the possibility that FDP impair activation and translocation of PKC from the PMN cytosolic to membrane fraction. Further studies to examine this include direct measures of PMN membrane fluidity in the presence of FDP and determination of whether FDP influences activation of PKC isolated from broken cells.

By analogy with the functional consequences of Fbg interaction with platelets (2, 5, 6), it might be expected that the observed effects of FDP on PMN activities are in part related to occupancy of Fbg binding sites. Although there are data indicating that promyeloid U937 cells possess GP IIb/IIIa, the molecular complex that represents the platelet Fbg receptor (59), recent reports suggest that circulating human PMN specifically bind Fbg via receptors that are similar or possibly identical to those for high molecular weight kininogen (60). Detailed molecular characterization of the interaction of FDP D and E with PMN and their functional effects on cells will require isolation of these receptor sites and use of highly purified preparations of fragments D₁ and E₃. Finally, the role of PMN proteases in modifying cellular responses to Fbg and FDP needs to be investigated (61, 62). The relevance of such molecules to PMN function has been suggested by recent observations of Wachtfogel and co-workers, who showed that fibronectin degradation products containing cytoadhesive peptide sequences identical to those in FDP (63) induce release of neutrophil elastase (64).
