Abstract

Monoamine oxidase (MAO) exists as two isoenzymes and plays a central role in the metabolism of monoamine neurotransmitters. In this study we compared the neurochemical phenotypes of previously described subjects with genetically determined selective lack of MAO-A or a lack of both MAO-A and MAO-B with those of two subjects with a previously described X chromosome microdeletion in whom we now demonstrate selective MAO-B deficiency. Mapping of the distal deletion breakpoint demonstrates its location in intron 5 of the MAO-B gene, with the deletion extending proximally into the Norrie disease gene. In contrast to the borderline mental retardation and abnormal behavioral phenotype in subjects with selective MAO-A deficiency and the severe mental retardation in patients with combined MAO-A/MAO-B deficiency and Norrie disease, the MAO-B–deficient subjects exhibit neither abnormal behavior nor mental retardation. Distinct neurochemical profiles characterize the three groups of MAO-deficient patients. In MAO-A–deficient subjects, there is a marked decrease in deaminated catecholamine metabolites and a concomitant marked elevation of O-methylated amine metabolites. These neurochemical changes are only slightly exaggerated in patients with combined lack of MAO-A and MAO-B. In contrast, the only biochemical abnormalities detected in subjects with the MAO-B gene deletion are a complete absence of platelet MAO-B activity and an increased urinary excretion of phenylethylamine. The differences in neurochemical profiles indicate that, under normal conditions, MAO-A is considerably more important than MAO-B in the metabolism of biogenic amines, a factor likely to contribute to the different clinical phenotypes. (J. Clin. Invest. 1996. 97:1010–1019.)

Key words: catecholamines • Norrie disease • metabolism • metanephrines • dihydroxyphenylglycol

Introduction

Monoamine oxidase (MAO),† an enzyme that plays a crucial role in the metabolic degradation of biogenic amines, exists in two functional forms: MAO-A and MAO-B (1–3). The two isoenzymes have different substrate and inhibitor specificities and are encoded by two genes on the short arm of the X chromosome (4).

Combined loss of MAO-A and MAO-B activity (MAO-AB) has been described in some patients with an X chromosome deletion that includes not only the Norrie disease gene but also the MAO-A and MAO-B genes (5–9). In addition to the blindness, hearing loss, and variable mental retardation that characterize Norrie disease (10), patients with the additional deletion of both MAO genes show profound mental retardation, autistic-like behavior, atomic seizures, altered peripheral autonomic function, and profound alterations in biogenic amine metabolism (5, 6, 8). More recently, selective loss of MAO-A activity due to a point mutation in exon 8 of the MAO-A gene was described in a Dutch kindred (11, 12). In this kindred, selective MAO-A deficiency was associated with a clinical phenotype characterized by borderline mental retardation and impaired impulse control, including a propensity towards stress-induced aggression.

Understanding the consequences of genetic deficiencies of MAO isoenzymes requires an understanding of the role of these enzymes in the metabolism of biogenic amines. In addition to inactivating catecholamines and their O-methylated metabolites, MAO deaminates other biogenic amines including 5-hydroxytryptamine (5-HT) and the trace amines phenylethylamine, m-tyramine, and p-tyramine (13). The catecholamines and their deaminated metabolites are also subject to O-methylation by catechol-O-methyltransferase (COMT). MAO and COMT, in combination with alcohol dehydrogenase, are responsible for the production of a wide range of catecholamine metabolites, which for the purpose of this study can be divided into two groups: deaminated metabolites and O-methylated amine metabolites (Fig. 1).

The redundant nature of catecholamine metabolism enables one pathway to compensate for blockade of the other, so

1. Abbreviations used in this paper: COMT, catechol-O-methyltransferase; DA, dopamine; DHPG, dihydroxyphenylglycol; DOPA, dihydroxyphenylalanine; DOPAC, dihydroxyphenylacetic acid; EPI, epinephrine; 5-HT, 5-hydroxytryptamine; HVA, homovanillic acid; MAO, monoamine oxidase; MHPG, methoxyhydroxyphenylglycol; VMA, vanillylmandelic acid.
that reduced or absent activity of MAO leads to a decrease in production of deaminated metabolites and an increase in that of O-methylated amine metabolites (14, 15). Thus, simultaneous measurements of these metabolites are useful for neurochemical phenotyping of patients with disorders of catecholamine metabolism (16).

The relative roles of COMT and MAO in the metabolic degradation of catecholamines are well established; on the other hand, those of the isoenzymes of MAO are not clear but are important for understanding the basis of therapeutic interventions involving specific inhibition of one or the other of the two MAO isoenzymes. Additionally, establishing the relative roles of MAO-A and MAO-B may also provide insight into how neurochemical alterations associated with deficiencies of the two isoenzymes give rise to clinical syndromes.

In the present study, we report on two subjects with a hitherto undescribed selective deficiency of MAO-B due to a microdeletion of the X chromosome, extending from the Norrie disease gene to within the MAO-B gene (17). For comparison, the neurochemical characteristics of previously described patients with combined MAO-AB deficiency and selective MAO-A deficiency are reported in greater detail, including a comprehensive analysis of plasma catecholamine metabolites (Fig. 1). These comparisons enabled examination of the relative roles of MAO-A and MAO-B in the metabolic degradation of catecholamines and other biogenic amines, including 5-HT and the trace amines.

**Methods**

**Subjects.** Two brothers (ages: 29 and 31 yr) with a complete selective loss of MAO-B activity due to a microdeletion of the Norrie disease and MAO-B genes participated in the study. Norrie disease, characterized by blindness, was diagnosed at the ages of 5 and 18 mo. Progressive hearing loss due to cochlear degeneration was noticed in adolescence in these subjects. Two male members (ages: 24 and 34 yr) of an unrelated Dutch family with a complete selective deficiency of MAO-A were also included in this study. Affected males in this family have a point mutation of the MAO-A gene and are characterized clinically by borderline mental retardation and impaired impulse control (11, 12). In addition, the study included five male subjects (age: 12–23 yr) from three different families, with a microdeletion of the X chromosome, including the Norrie disease gene and the MAO-A and MAO-B genes (5–9). These latter subjects are characterized clinically by blindness and profound mental retardation.

29 males aged 21–55 yr (mean±SD: 35±9 yr) served as a reference group for measurements of plasma catecholamines and metabolites. Subjects were not taking any medications and were all in good health as determined by a negative medical history and a normal physical examination. These subjects were enlisted for study at two different institutions, The Clinical Center, National Institutes of Health (NIH), and the St. Radboud University Hospital. All procedures were approved by the appropriate review committees, and informed consent was obtained for all studies.

**Procedures.** Baseline venous blood samples were drawn after 15 min of rest, and plasma and platelet-rich plasma were separated by centrifugation at 4°C. Samples of plasma and platelet-rich plasma were stored at –80°C until assayed for concentrations of catecholamines, metabolites, and 5-HT (8), and activities of platelet MAO-B and plasma amine oxidase. 24-h urine samples were collected and acidified to pH 2–3, and 20-ml aliquots were stored at –25°C until assayed. The two subjects with selective MAO-A deficiency received a simultaneous infusion of [3H]labeled NE and epinephrine (EPI) (1–2,5,6-[3H]NE, 40–60 Ci/mmol; t-N-methyl-[3H]EPI, 65–75 Ci/mmol [DuPont-New England Nuclear, ’s Hertogenbosch, The Netherlands]) to calculate forearm spillovers of NE and normetanephrine (18). In these two subjects, a standardized tyramine infusion was also carried out to determine tyramine pressor sensitivity (19). To compare neurochemical abnormalities in MAO-deficient subjects with changes occurring after pharmacological inhibition of MAO, 11 male subjects (mean±SD ages: 37±9 yr) with attention deficit hyperactivity disorder were studied before and after administration of deprenyl at a dose (60 mg daily for 6 wk) sufficient to inhibit both MAO-A and MAO-B (19).

**DNA/genetic analysis.** Genomic DNA in the two MAO-B-deficient subjects was isolated from peripheral blood as described previously (20). DNA was digested by the restriction enzymes EcoRI, transferred to nylon membranes by Southern blotting, and hybridized to either [3P]-labeled cosmid C5 (17) or to an MAO-B cDNA probe containing exons 3–15 (21). Hybridizing bands were visualized by overnight exposure of the membrane to film (X-omat S; Eastman Kodak Co., Rochester, NY). Hybridizing fragments were assigned to either DNA segment on the basis of published data (22).

**Enzyme activities and platelet 5-HT.** Platelet-rich plasma was prepared by differential centrifugation using EDTA or acid citrate dextrose as anticoagulants. Platelet MAO-B and plasma amine oxidase activities were measured at the NIH, using 200 μM methylene-[14C]benzylamine (50 Ci/mmol; ICN Biomedicals Inc., Irvine, CA) as substrate (23). Measurements of platelet MAO activity were also carried out at the Academic Medical Center (Amsterdam, The Netherlands) using a fluorimetric method with kynuramine as substrate (24).
Platelet concentrations of 5-HT were measured at the NIH as described previously (5).

**Plasma neurochemical assays.** All assays of plasma catecholamines and their metabolites were carried out at the NIH. The catecholamines NE, EPI, and dopamine (DA); the deaminated catecholamine metabolites 3,4-dihydroxyphenylglycol (DHPG) and dihydroxyphenylacetic acid (DOPAC); and the catecholamine precursor dihydroxyphenylalanine (DOPA) were extracted from 1-ml samples of plasma using alumina and quantified by liquid chromatography with electrochemical detection (25). The metanephrines—normetanephrine and metanephrine, O-methylated amine metabolites of NE and EPI, respectively—were extracted from 2-ml samples of plasma using solid-phase ion exchange columns and quantified by liquid chromatography with electrochemical detection (26). Timed collections of the catecholamine and metanephrine eluants leaving the electrochemical cell, followed by liquid scintillation spectroscopy, were used to determine plasma concentrations of 3H-labeled catecholamines and metanephrines. Concentrations of sulfate-conjugated metanephrines were determined after deconjugation by incubation with sulfatase (Sigma Chemical Co., St. Louis, MO). Liquid chromatography with electrochemical detection was also used for measurement of the deaminated NE metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), after extraction from plasma into ethylacetate (27). Concentrations of the DA metabolite, homovanillic acid (HVA), and of the final deaminated end-product of NE and EPI metabolism, vanillylmandelic acid (VMA), were measured by gas chromatography–mass spectrometry after ethylacetate extraction and derivatization with pentafluoropropionic anhydride (28).

**Urine neurochemical assays.** Urine concentrations of catecholamines and their metabolites were determined at two centers: the NIH and the Academic Medical Center. These measurements were carried out using gas chromatography–mass spectroscopy at the NIH (8, 28) and liquid chromatography with fluorometric detection at the Academic Medical Center (29, 30). Urine concentrations of 5-HT were also measured at the latter center using liquid chromatography with fluorometric detection. Urine concentrations of trace amines (phenylethylamine, m-tyramine, and p-tyramine) were assayed at St. Elizabeth’s Hospital (Washington, DC) by gas chromatography–mass spectroscopy as described previously (31). Urine concentrations of catecholamines and their metabolites are reported as total concentrations (free and conjugated). Some of the urine data for the MAO-AB– and MAO-A–deficient subjects have been reported elsewhere (5, 6, 8, 11).

**Data analysis.** The mean and SD of the plasma concentrations of catecholamines and metabolites in the 29 control subjects were calculated and served as the reference group for the tabulated data. Reference values for urine catecholamines and their metabolites were used from the original published methods. Differences between MAO-deficient subjects and control groups were tested by the Mann-Whitney U test. Within subject differences were determined using the Wilcoxon signed rank sum test. Differences were considered significant at P < 0.05 (two tailed). All values in the text are presented as mean ± SEM, unless indicated otherwise.

**Results**

**Clinical characteristics of the MAO-B–deficient subjects.** A general physical examination of the two brothers with the MAO-B deficiency, including global neurological examination, was unremarkable. They have normal blood pressure and heart rate. They are blind and have impaired hearing as part of Norrie disease. Psychomotor development is normal. Both subjects have completed university degrees.

**Delineation of the X chromosome microdeletion.** We have previously reported that the deletion in these two brothers with Norrie disease extends from within the Norrie disease gene on the proximal side to within the MAO-B gene (17). Precise mapping of the deletion breakpoint was achieved by hybridization of the patients DNA to 13 cosmids derived from a 300-kb contig that encompasses the MAO-B and Norrie disease genes. In this way, the size of the deletion was estimated to be 150 kbp. Moreover, when cosmid C5 was used as a hybridization probe on EcoRI-digested genomic DNA, four of the nine fragments were absent in the patient, and a putative deletion junction fragment of 2.5 kbp appeared (Fig. 2, left). Cosmid C5 had been shown previously to cover most of the MAO-B and Norrie disease genes. In this way, the size of the deletion was estimated to be 150 kbp. Moreover, when cosmid C5 was used as a hybridization probe on EcoRI-digested genomic DNA, four of the nine fragments were absent in the patient, and a putative deletion junction fragment of 2.5 kbp appeared (Fig. 2, left). Cosmid C5 had been shown previously to cover most of the MAO-B gene (17).

Deletion of the 5′ end of the MAO-B gene was confirmed by hybridizing the same Southern blot to a cDNA probe containing exons 3–15 of the MAO-B gene. This experiment demonstrated deletion of exons 3–5 and an altered size of the fragment containing exon 6 (Fig. 2, right). Based on these results, the distal deletion breakpoint is located in intron 5.
MAO-A deficiency. The activity of plasma amine oxidase was normal in all three subject groups (Table I).

Platelet 5-HT. The 5-HT content of platelets was within normal limits in the two subjects with MAO-B deficiency, whereas it was increased considerably in the groups with selective MAO-A and combined MAO-AB deficiencies (Table I).

Plasma concentrations of catecholamines and metabolites. Plasma concentrations of NE and EPI were within the normal range in all MAO-deficient subjects (Table II). Plasma concentrations of DA were also normal in the subjects with selective deficiencies of MAO-B or MAO-A, whereas they were higher in patients with the combined MAO-AB deficiency than in control subjects (0.19±0.06 vs 0.07±0.01 pmol/ml; P < 0.05). Plasma concentrations of free and sulfate-conjugated normetanephrine and metanephrine, the O-methylated amine metabolites of NE and EPI, were normal in MAO-B–deficient subjects, whereas both groups of MAO-A– and MAO-AB–deficient subjects showed considerable elevations above normal in plasma concentrations of free and sulfate-conjugated normetanephrine and sulfate-conjugated metanephrine (Table II). In contrast, all MAO-deficient subjects, apart from one MAO-AB–deficient patient (number 6), showed normal or only slightly elevated plasma concentrations of free metanephrine. Thus, plasma concentrations of sulfate-conjugated metanephrine in MAO-A– and MAO-AB–deficient subjects were elevated above mean concentrations of normal subjects more than concentrations of free metanephrine (4.5±0.53 vs 2.1±0.7-fold increase; P < 0.03). Similarly, plasma concentrations of sulfate-conjugated normetanephrine showed larger elevations in MAO-A– and MAO-AB–deficient subjects than concentrations of free normetanephrine (13.2±3.0 vs 6.5±0.6-fold increase; P < 0.02). Increases in plasma concentrations of free and sulfate-conjugated normetanephrine were larger (P < 0.02) than those of metanephrine.

Plasma concentrations of DHPG, the deaminated metabolite of NE and EPI, were normal in MAO-B–deficient subjects, whereas they were reduced by > 95% in MAO-A subjects and undetectable in four of the five subjects with combined MAO-AB deficiency (Table II). A similar pattern

Compounds with abnormal levels are depicted in bold. NMN, normetanephrine; NMN-SO₄, sulfate-conjugated normetanephrine; MN, metanephrine; MN-SO₄, sulfate-conjugated metanephrine.

was observed for MHPG and VMA, the deaminated and O-methylated metabolites of NE and EPI; these metabolites were normal in MAO-B–deficient subjects, whereas they were reduced by 75–92% in the two MAO-A–deficient subjects and reduced further to >93% in the subjects with the combined MAO-AB deficiency.

Since plasma concentrations of DHPG and sulfate-conjugated normetanephrine showed the largest reciprocal changes in MAO-AB–deficient subjects, the ratios of these metabolites were compared with those in normal subjects and patients receiving the MAO inhibitor, deprenyl (Fig. 4). Ratios of plasma concentrations of sulfate-conjugated normetanephrine to DHPG were within the normal range in the MAO-B–deficient subjects, whereas these ratios were elevated by ~100-fold in the MAO-A–deficient subjects and by more than several thousand–fold in all five subjects with the combined MAO-AB deficiency. Similarly, in the subjects who received deprenyl, a 250% increase in conjugated normetanephrine and a 60% decrease in plasma concentrations of DHPG resulted in an increase in the ratio of these two metabolites.

The deaminated metabolites of DA, DOPAC, and HVA showed a less marked and more variable trend than that observed for the deaminated metabolites of NE and EPI (Table II). Again, plasma concentrations of these metabolites were normal in the two MAO-B–deficient subjects but reduced by 53–60% in the MAO-A–deficient subjects. Plasma DOPAC and HVA tended to be reduced more in the combined MAO-AB–deficient subjects than in the two MAO-A–deficient subjects, but there was considerable variability. In particular, one subject with combined MAO-AB deficiency showed normal concentrations of both DOPAC and HVA.

Plasma levels of DOPA, the catecholamine precursor, were normal in MAO-B–deficient subjects (7.65 and 7.54 nmol/liter), but significantly lower in subjects with selective MAO-A and combined MAO-AB deficiencies than in control subjects (5.64±0.44 vs 8.55±0.40 nmol/liter, respectively; \(P<0.01\)).

Urinary excretion of catecholamines, catecholamine metabolites, 5-HT, and trace amines. The only abnormal neurochemical finding in the MAO-B–deficient subjects was an increase in urinary phenylethylamine levels (Table III). Urinary excretion of the other trace amines, meta- and paratyramine, was normal, as was that of the catecholamines, their O-methylated and deaminated metabolites, and 5-HT.

In contrast to the MAO-B–deficient subjects, the two subjects with a selective deficiency of MAO-A showed increased excretion of 5-HT, normetanephrine, and the O-methylated amine metabolite of DA, 3-methoxytyramine (11). These subjects also showed decreased or low-normal urinary excretion of the deaminated metabolites, MHPG, VMA, and HVA. Excretion of all trace amines was within normal limits.

In subjects with the combined MAO-AB deficiency, the urinary excretion of catecholamines and their metabolites

Compounds with abnormal values are depicted in bold. Academic Medical Center Amsterdam control values for catecholamines, catecholamine metabolites, and 5-HT apply to subjects 1–4 and 9. National Institutes of Health control values for catecholamines and catecholamine metabolites apply to subjects 5–8. All trace amines were assayed at St. Elizabeth’s Hospital, Washington, DC.

showed similar qualitative alterations as in subjects with the selective MAO-A deficiency but tended to be more variably disturbed (Table III). In particular, excretion of HVA showed highly variable changes compared with other subject groups. Similar to the situation in plasma, urinary levels of DA were also increased in patients with combined MAO-AB deficiencies but not in those with selective deficiencies of either isoenzyme.

Excretion of all trace amines was profoundly increased in patients with combined MAO-AB deficiency. In particular, excretion of phenylethylamine was increased substantially more in combined MAO-AB–deficient subjects than in selective MAO-B–deficient subjects. Furthermore, whereas excretion of the tyramine trace amine was normal in subjects with either selective deficiency of MAO-A or MAO-B, it was increased considerably in subjects with the combined MAO-AB deficiency.

**Forearm spillover of NE and normetanephrine in MAO-A deficiency.** Use of the tracer-labeled NE and EPI isotope dilution technique indicated an increase in forearm spillover into plasma of normetanephrine in the two MAO-A–deficient subjects (Table IV). Forearm spillovers of normetanephrine from both circulating and locally released NE were increased. Forearm spillover of NE was also increased in one of these subjects.

**Tyramine sensitivity test.** In one of the two MAO-A–deficient subjects, systolic blood pressure was increased to the 30-mmHg end-point by an intravenous dose of tyramine of only 0.11 mg/min; this represents a dose less than one-tenth of that required in a control group of 11 patients with depression (19), and comparable to that in patients treated with selective MAO-A and nonselective MAO inhibitors (32), but about fourfold more than the end-point dose required in a juvenile patient with combined MAO-AB deficiency (5). In the other MAO-A–deficient subject, the tyramine infusion had to be stopped prematurely at an infusion rate of 0.03 mg/min because of persisting Oppressing pain in his chest. Systolic blood pressure had increased by 5 mmHg at this infusion rate.

**Discussion**

This is the first description of patients with a selective loss of MAO-B activity due to a disruption of the MAO-B gene on the X chromosome. This is also the first comprehensive report comparing neurochemical and clinical phenotypes in patients with selective deficiencies of MAO-A and MAO-B and combined deficiencies of MAO-AB. The results demonstrate that the three groups of patients each display characteristic neuro-
chemical profiles that may contribute to the different clinical phenotypes of each group.

**Genotype and clinical phenotype of MAO-B deficiency patients.** In addition to a partial deletion of the MAO-B gene, the gene for Norrie disease is also involved in the syndrome affecting these two brothers. In fact, these patients were originally described as part of a previous study of Norrie disease that resulted in the cloning of the Norrie disease gene (17). Although these subjects show the characteristic features of Norrie disease, namely early onset blindness and progressive hearing loss, they show no signs of physical or mental impairment. In particular, no signs of mental retardation or behavioral disturbances have been noted as are observed in patients with classical Norrie disease combined with MAO-AB deficiency (5–8) or in subjects with selective MAO-A deficiency (11, 12). Only a part of the MAO-B gene is deleted, but since this includes the DNA sequence encoding the first 159 amino acids of MAO-B, this is incompatible with any functional MAO-B activity. A complete and selective lack of MAO-B is documented by the undetectable levels of platelet MAO-B activity, determined by two different assay techniques, and is also reflected in the increased urinary phenylethylamine levels that are characteristically found with reduced MAO-B activity (33).

**Metabolic roles of MAO isoenzymes.** Comparison of the selective deficiencies of MAO-A and MAO-B and combined deficiency of MAO-AB provides a unique insight into the metabolic roles of the MAO isoenzymes in humans. This insight is not only important for interpreting the clinical consequences of MAO deficiency states, but also for understanding the basis of therapeutic interventions involving selective inhibition of MAO-A or MAO-B. Up until now, studies of the metabolic roles of MAO-A and MAO-B have been confined largely to pharmacological studies in animals or isolated tissues. Such studies are limited by a lack of completely selective MAO inhibitors as well as by difficulties in extrapolating the function of MAO from isolated tissues or animals to humans (3).

The severely impaired deamination of catecholamines in subjects with combined MAO-AB deficiency is demonstrated by the > 93% reductions in plasma concentrations of the deaminated catecholamine metabolites, DHPG, MHPG, and VMA. Additionally, the markedly elevated plasma concentrations of O-methylated amine metabolites—free and sulfate-conjugated normetanephrine and sulfate-conjugated metanephrine—reflect impaired deamination of these metabolites as well as increased availability of the parent amines for O-methylation (14). Slightly less severe changes in patients with selective MAO-A deficiency and complete lack of similar directional changes in MAO-B–deficient subjects indicate that MAO-A is considerably more important than MAO-B for metabolism of NE, EPI, and their O-methylated amine metabolites in vivo. These findings agree with those in rats (14), where pharmacological inhibition of MAO-B failed to affect either the deaminated or O-methylated amine metabolites of NE and EPI, whereas inhibition of MAO-A resulted in similar directional changes to those observed here.

Larger increases in plasma concentrations and urinary excretion of normetanephrine than of metanephrine are also in agreement with results in rats or humans administered MAO inhibitors, a difference attributed to little deamination of EPI and metanephrine in the compartment where metanephrine is formed (14, 15). The larger increases in plasma concentrations of sulfate-conjugated than free metanephrines can be explained similarly by compartmental differences in sites of formation. Over 90% of free metanephrine and a substantial, but lower, portion of free normetanephrine are formed within the adrenals (16, 18). In contrast, the conjugated metanephrines are not formed within the adrenals, but are formed elsewhere in the body where deamination is a more prominent pathway than in the adrenals.

As previously described (12), cultured skin fibroblasts of the two subjects with the selective MAO-A deficiency had no MAO-A activity. The present study extends the observation of MAO-A deficiency to the organ level and documents impaired extraneuronal deamination of NE and normetanephrine as indicated by the increased forearm spillover of normetanephrine from locally released and circulating NE.

According to a study in isolated human brain tissue, DA was proposed as a selective substrate for MAO-B (34). However, studies of substrate specificity of the two forms of MAO in isolated tissues do not always reflect reliably the situation in vivo, and it has now been established that, under physiological conditions, DA is also a substrate for MAO-A (3). The decreases in plasma DOPAC and HVA, decreases in urinary excretion of HVA, and increases in urinary excretion of the O-methylated DA metabolite, 3-methoxytyramine, in MAO-A–deficient subjects support an important role for MAO-A in the metabolism of DA. This finding and the complete lack of any similar directional changes in the MAO-B–deficient subjects are in agreement with the results of individual blockade of the two isoenzymes in rats (14) and raise questions about whether MAO-B has any physiological role in the normal in vivo metabolism of DA.

The substantial decreases in deaminated catecholamine metabolites and increases in O-methylated amine metabolites in MAO-A–deficient but not MAO-B–deficient subjects indicate that the two isoenzymes do not have equal complementary capacities for the deamination of catecholamines when one of the two isoenzymes is lacking. Nevertheless, the somewhat exaggerated neurochemical changes in patients with combined MAO-AB deficiency compared with selective MAO-A deficiency indicate that MAO-B plays a minor auxiliary role in the metabolism of catecholamines when the activity of MAO-A is impaired. This conclusion is further supported by the elevated plasma concentrations and urinary excretion of DA in MAO-AB–deficient subjects, but not in other groups. In rats, combined inhibition of the two MAO isoenzymes reduces the deamination of intravenously infused NE more than inhibition of MAO-A alone, whereas inhibition of MAO-B alone has no effect (14). The results indicate that, under normal conditions, MAO-B does not have a major role in the deamination of catecholamines. Normal urinary and platelet levels of 5-HT in MAO-B–deficient subjects and substantial increases in selective MAO-A– and combined MAO-AB–deficient subjects also suggest that MAO-B is of less importance than MAO-A for the in vivo metabolism of 5-HT.

An important role for MAO-B is, however, evident for deamination of the trace amines, phenylethylamine and para- and metatyramine. Increased urinary phenylethylamine in MAO-B–deficient subjects represents the only neurochemical abnormality we could detect in these subjects. This increase contrasted with normal urinary phenylethylamine levels in MAO-A–deficient subjects, findings consistent with the reported preferential deamination of phenylethylamine by MAO-B (1,
that characterize these patients. These data do not, however, exclude a possible neuronal regulatory function of phenylethylamine in central nervous system catecholamine systems (46).

Despite the predominance of MAO-B over MAO-A in the human brain (3), the prominent disturbances in behavior in MAO-A-deficient subjects and the normal behavior in MAO-B-deficient subjects indicate that MAO-A plays a more vital role than MAO-B in the normal neurophysiological development and function. This conclusion is consistent with the considerably more important role of MAO-A compared with MAO-B in the metabolism of catecholamines and 5-HT revealed by the present study. However, whether any of the profound neurochemical derangements observed in MAO-A-deficient subjects reflect the physiological basis of the behavioral disorder in these subjects remains to be established.

A relationship between the observed neurochemical and behavioral abnormalities in MAO-A-deficient subjects is strongly supported by a recent study in transgenic mice with a deletion in the MAO-A gene (47). The severe behavioral disturbances in these animals were associated with markedly elevated brain 5-HT concentrations and could be reversed by postnatal administration of a 5-HT synthesis inhibitor. A causal relationship between altered 5-HT metabolism and disturbed behavior was suggested to be mediated by discrete cortical alterations induced by chronically elevated 5-HT levels. Further support for involvement of altered 5-HT metabolism is provided by another recent study, in which behavioral disturbances in rats administered MAO inhibitors, before and after birth, were also associated with structural changes in brain serotonergic systems (48). We have previously argued that the possible disruptive effect of raised 5-HT levels on the developing brain may help explain why impulsive aggressive behavior has been consistently associated with low levels of 5-HT or its primary metabolite, 5-hydroxyindolacetic acid, whereas 5-HT levels are elevated in subjects with selective MAO-A deficiency who show similar behavior (49).

The patients with combined deletions of the MAO-A and MAO-B genes also have deletions of the Norrie disease gene. However, the severe neurological symptoms and mental retardation in these patients are not universal characteristics of patients with Norrie disease (8, 16). This is illustrated by the present patients with deletions of the MAO-B and Norrie disease genes, both of whom had completed university degrees and in whom the only symptoms were the early onset blindness and impaired hearing. Despite the essentially normal neurochemical profile in MAO-B-deficient patients, those with combined MAO-AB deficiency had somewhat more severe neurochemical changes than MAO-A-deficient patients, suggesting that MAO-B may compensate, albeit to a limited extent, for lack of MAO-A. Thus, it is possible that the much more severe mental retardation and other neurological abnormalities observed in patients with combined MAO-AB (compared with selective MAO-A deficiency) are due to additional deletion of the MAO-B gene. However, since the patients with combined MAO-AB deficiency have deletions of various sizes that possibly involve other genes on the X chromosome, other explanations should also be considered.

Neurochemical phenotyping may provide a sensitive tool for detection of the MAO-A deficiency state. In contrast to laborious methods of direct DNA analysis and measurements of fibroblast MAO-A activities, measurement of plasma catecholamine metabolites provides a relatively simple screening
procedure. In particular, use of the ratio of plasma concentrations of sulfate-conjugated normetanephrine to plasma DHPG, which are the metabolites that show the most dramatic changes, provides a sensitive method for the detection of subjects suspected of having reduced activity of MAO-A.

In conclusion, selective deficiency of MAO-B does not lead to a specific clinical phenotype and, in particular, is not associated with clinically apparent disturbances in behavior such as are observed in deficiencies of MAO-A. The absence in MAO-B-deficient patients of the severe neurochemical alterations observed in patients with deficiencies of MAO-A or MAO-AB indicates that MAO-A is considerably more important than MAO-B for metabolism of most biogenic amines. These functional differences in the two isoenzymes of MAO are likely to contribute to the different clinical phenotypes observed in patients with deficiencies of either or both isoenzymes and may help in understanding the basis for therapeutic interventions involving specific inhibition of one or the other isoenzymes.

Acknowledgments

We gratefully acknowledge the contributions of our many co-authors on previously published papers who helped characterize the genetic, neurochemical, and behavioral features of the subjects reviewed in this paper. We also gratefully acknowledge the technical assistance of Jacques Willemsen, Douglas Hooper, Teresa Tolliver, and Jerry Oliver and the help of Marie-Cecile Jacobs in the studies of catecholamine kinetics.
