Accumulation of cholesteryl esters (CEs) in macrophage foam cells, central to atherosclerotic plaque formation, occurs as a result of imbalance between the cholesterol influx and efflux pathways. While the uptake, or influx, of modified lipoproteins is largely unregulated, extracellular acceptor-mediated free cholesterol (FC) efflux is rate limited by the intracellular hydrolysis of CE. We previously identified and cloned a neutral CE hydrolase (CEH) from human macrophages and demonstrated its role in cellular CE mobilization. In the present study, we examined the hypothesis that macrophage-specific overexpression of CEH in atherosclerosis-susceptible Ldlr−/− mice will result in reduction of diet-induced atherosclerosis. Transgenic mice overexpressing this CEH specifically in the macrophages (driven by scavenger receptor promoter/enhancer) were developed and crossed into the Ldlr−/− background (Ldlr−/−CEHTg mice). Macrophage-specific overexpression of CEH led to a significant reduction in the lesion area and cholesterol content of high-fat, high-cholesterol diet–induced atherosclerotic lesions. The lesions from Ldlr−/−CEHTg mice did not have increased FC, were less necrotic, and contained significantly higher numbers of viable macrophage foam cells. Higher CEH-mediated FC efflux resulted in enhanced flux of FC from macrophages to gall bladder bile and feces in vivo. These studies demonstrate that by enhancing cholesterol efflux and reverse cholesterol transport, macrophage-specific overexpression of CEH is antatherogenic.

Introduction

Presence of cholesteryl ester–laden (CE-laden) macrophage foam cells is one of the most prominent characteristics of an atherosclerotic lesion. Foam cells develop in the vessel wall as a result of migration of circulating monocytes into the intima, differentiation into macrophages, and uptake of excessive amounts of retained and modified plasma lipoproteins. CEs associated with the lipoproteins are hydrolyzed in late endosomes/lysosomes to free cholesterol (FC), which then traffics to and integrates into the plasma membrane (1). Excess membrane cholesterol and a fraction of LDL-derived FC is transported to endoplasmic reticulum where it is reesterified by acyl CoA:cholesterol acyltransferase 1 (ACAT-1) and stored in cytoplasmic lipid droplets. While this reesterification of cholesterol is initially beneficial to the cells in preventing the FC-associated cell toxicity, under conditions of unregulated or increased uptake of modified LDL, it leads to excessive accumulation of CE present as cytoplasmic lipid droplets, giving the cells their characteristic “foamy” appearance. Extracellular acceptor-mediated cholesterol efflux is the primary mechanism for removal of cellular cholesterol and is critical in preventing foam cell formation and atherosclerotic lesion development. However, in order for efflux to occur, FC must first be released from stored CE by hydrolysis mediated by a neutral CE hydrolase (CEH), and this step is increasingly being recognized as the rate-limiting step in FC efflux (2).

Despite the obvious significance of CE hydrolysis in cellular FC efflux, limited efforts have been directed toward manipulating this step as a potential target for pharmacological or genetic intervention of foam cell formation. The main reason had been the controversy surrounding the identity of neutral CEH(s) in macrophages. Although several lines of evidence initially suggested that the enzyme responsible for CE hydrolysis in murine macrophages is similar to hormone-sensitive lipase (Hsl), which is present in adipose and steroidogenic tissues (3–5), identical levels of CE hydrolysis were observed in peritoneal macrophages isolated from wild-type or Hsl knockout mice (6, 7), suggesting that an enzyme other than Hsl is responsible for catalyzing CE hydrolysis in murine macrophages. Further, Hsl-transgenic mice developed 2–3 times larger lesions, and macrophages from these animals stored correspondingly higher concentrations of CE when incubated with acetylated LDL (AcLDL) (8), indicating a limited role, if any, of Hsl in cholesterol removal from macrophages. Li and Hui reported the absence of Hsl in human macrophages and demonstrated the expression of bile salt–stimulated CEH, similar to secretory pancreatic carboxyl ester lipase (Cel) (9). However, macrophage-specific transgenic expression of this Cel increased CE accumulation and promoted atherosclerosis (10), confirming

Nonstandard abbreviations used: ACAT-1, acyl CoA:cholesterol acyltransferase; AcLDL, acetylated LDL; CE, cholesteryl ester; CEH, CE hydrolase; CEL, carboxyl ester lipase; FC, free cholesterol; FPLC, fast protein liquid chromatography; HSL, hormone-sensitive lipase; Ldrl−/−, LDL receptor–null (mice).

CEH-transgenic mice were identified by PCR amplification of tail DNA. One founder line in C57BL/6 background and 7 in Balb-c/C57BL/6 hybrid background were obtained. The transgenic founder line in C57BL/6 background and 2 of 7 founder lines in Balb-c/C57BL/6 hybrid background were analyzed for tissue distribution of CEH. Similar expression profiles were obtained with all 3 lines, and data for the C57BL/6 founder line is shown in Figure 1. While CEH expression was seen in liver, lung, spleen, kidney, and heart, significantly higher expression was seen in macrophages, consistent with the use of the SR-A promoter/enhancer (15). Consistent with increased CEH mRNA expression, a 64% increase in CEH activity (399 ± 72.5 versus 656 ± 67.9 pmol/h/mg, n = 3, P < 0.05) was associated with thioglycollate-elicited peritoneal macrophages from transgenic founder mice. This increase in the level of increase in CEH activity, which is fairly modest and potentially in the physiological range, significantly reduced cellular CE levels in agmACAT1 and THP1 macrophages (13, 14). Since there was no significant difference in CEH expression between the 3 founder lines tested, the line in pure C57BL/6 background was chosen for further studies after crossing into the Ldlr−/− background.

Macrophage-specific transgenic expression of CEH did not alter the plasma cholesterol levels. Plasma was obtained from non-fasted Ldlr−/− and Ldlr−/−CEHTg mice fed a Western type, high-fat, high-cholesterol diet for 16 weeks and was analyzed for total cholesterol and distribution of cholesterol among lipoprotein fractions. As shown in Figure 2 and Table 1, there was no significant difference in the fast protein liquid chromatography (FPLC) profiles, total plasma cholesterol, or the distribution of cholesterol among the plasma lipoproteins, suggesting that macrophage-specific expression of CEH does not alter plasma or lipoprotein cholesterol concentrations.

Macrophage-specific transgenic expression of CEH significantly reduced the atherosclerotic lesion area. Atherosclerosis was assessed in mice fed Western type, high-fat, high-cholesterol diet for 16 weeks. The percent area of aorta covered with atherosclerotic lesions was determined by en face analyses, and Figure 3A shows representative images of aortae obtained from Ldlr−/− and Ldlr−/−CEHTg mice. While very few lesions were noticeable in the thoracic and abdominal aortae as expected with this mouse model, the aortic arch displayed the most profound lesions. A marked decrease in atherosclerotic lesion area was observed in the aortic arch (Figure 3B) of CEH-transgenic mice. The quantification of the surface area occupied by atherosclerotic lesions is shown in Figure 3C. Compared with Ldlr−/− mice, transgenic expression of CEH in Ldlr−/−CEHTg mice led to a significant decrease in percent area occupied by atherosclerotic lesions in the aortic arch (27.5 ± 2.53 versus 14.09 ± 1.18 in males, P = 0.0008; 22.7 ± 1.94 versus 11.14 ± 1.04 in females, P = 0.004).

### Figure 1
Macrophage-specific expression of the human CEH transgene. Total RNA was isolated from liver, lung, spleen, kidney, heart, and thioglycollate-elicited peritoneal macrophages. CEH mRNA expression was determined by real-time PCR as described in Methods. Data (mean ± SD, n = 3) from founder line in C57BL/6 background are expressed as CEH copy no./ng total RNA. Similar results were obtained from the 2 founder lines in Balb-c/C57BL/6 hybrid background that were also tested.

### Results
**Development of CEH-transgenic mice.** CEH-transgenic mice were identified by PCR amplification of tail DNA. One founder line in C57BL/6 background and 7 in Balb-c/C57BL/6 hybrid background were obtained. The transgenic founder line in C57BL/6 background and 2 of 7 founder lines in Balb-c/C57BL/6 hybrid background were analyzed for tissue distribution of CEH. Similar expression profiles were obtained with all 3 lines, and data for the C57BL/6 founder line is shown in Figure 1. While CEH expression was seen in liver, lung, spleen, kidney, and heart, significantly higher expression was seen in macrophages, consistent with the use of the SR-A promoter/enhancer (15). Consistent with increased CEH mRNA expression, a 64% increase in CEH activity (399 ± 72.5 versus 656 ± 67.9 pmol/h/mg, n = 3, P < 0.05) was associated with thioglycollate-elicited peritoneal macrophages from transgenic founder mice. This increase in the level of increase in CEH activity, which is fairly modest and potentially in the physiological range, significantly reduced cellular CE levels in agmACAT1 and THP1 macrophages (13, 14). Since there was no significant difference in CEH expression between the 3 founder lines tested, the line in pure C57BL/6 background was chosen for further studies after crossing into the Ldlr−/− background.

Macrophage-specific transgenic expression of CEH did not alter the plasma cholesterol levels. Plasma was obtained from non-fasted Ldlr−/− and Ldlr−/−CEHTg mice fed a Western type, high-fat, high-cholesterol diet for 16 weeks and was analyzed for total cholesterol and distribution of cholesterol among lipoprotein fractions. As shown in Figure 2 and Table 1, there was no significant difference in the fast protein liquid chromatography (FPLC) profiles, total plasma cholesterol, or the distribution of cholesterol among the plasma lipoproteins, suggesting that macrophage-specific expression of CEH does not alter plasma or lipoprotein cholesterol concentrations.

Macrophage-specific transgenic expression of CEH significantly reduced the atherosclerotic lesion area. Atherosclerosis was assessed in mice fed Western type, high-fat, high-cholesterol diet for 16 weeks. The percent area of aorta covered with atherosclerotic lesions was determined by en face analyses, and Figure 3A shows representative images of aortae obtained from Ldlr−/− and Ldlr−/−CEHTg mice. While very few lesions were noticeable in the thoracic and abdominal aortae as expected with this mouse model, the aortic arch displayed the most profound lesions. A marked decrease in atherosclerotic lesion area was observed in the aortic arch (Figure 3B) of CEH-transgenic mice. The quantification of the surface area occupied by atherosclerotic lesions is shown in Figure 3C. Compared with Ldlr−/− mice, transgenic expression of CEH in Ldlr−/−CEHTg mice led to a significant decrease in percent area occupied by atherosclerotic lesions in the aortic arch (27.5 ± 2.53 versus 14.09 ± 1.18 in males, P = 0.0008; 22.7 ± 1.94 versus 11.14 ± 1.04 in females, P = 0.004).

### Figure 2
Distribution of cholesterol among plasma lipoprotein fractions. Plasma was obtained from non-fasted Ldlr−/− and Ldlr−/−CEHTg mice after 16 weeks of feeding. An aliquot of the plasma from each animal was applied to Superose 6 FPLC column (flow rate, 0.4 ml/min) and cholesterol content of individual lipoproteins determined by an online assay as described in Methods. A representative FPLC profile is presented showing a continuous online measurement of cholesterol (expressed as millivolts). n = 9 per genotype.
However, there was no significant decrease in the surface area occupied by the lesions in thoracic and abdominal aortae. Total area occupied by the lesions in the entire aorta was calculated by adding the corresponding areas in aortic arch and thoracic and abdominal aortae, and compared with Ldlr−/− mice, transgenic expression of CEH in Ldlr−/−CEHTg mice led to a significant decrease in total area occupied by the lesions (16.99 ± 0.96 versus 8.69 ± 0.55 in males, P = 0.0005; 14.21 ± 1.58 versus 7.79 ± 0.66 in females, P = 0.018). This reduction in the lesion area (about 50%) by transgenic expression of CEH was similar and not significantly different in male and female mice. These findings indicate that macrophage-specific CEH expression decreases diet-induced atherosclerosis in Ldlr−/− mice.

Aortic esterified cholesterol content of Ldlr−/−CEHTg mice is significantly lower than that of control Ldlr−/− mice. Aortic cholesterol content is a biochemical endpoint for evaluating atherosclerosis, and a strong positive correlation exists between area occupied by lesions and aortic cholesterol content (16). To evaluate the effect of transgenic expression of CEH on aortic esterified cholesterol (EC) content, total lipids were extracted from the 2 pieces of the aorta (aortic arch and thoracic and abdominal aortae) and cholesterol content (total cholesterol, FC, and EC) was determined. Consistent with CEH overexpression and reduced lesion area, the EC content of the aortic arch (Figure 4) was significantly lower (by 50%) in Ldlr−/−CEHTg mice compared with Ldlr−/− mice (116 ± 8.6 versus 63 ± 7.6 μg/mg protein, P = 0.001). In addition, the FC content was also lower in Ldlr−/−CEHTg mice (129 ± 15.8 versus 60 ± 7 μg/mg protein, P = 0.009) but the ratio of EC to FC remained essentially unchanged.

Lesions from Ldlr−/−CEHTg mice are cellular. Massive accumulation of FC and CE in advanced lesions results in necrotic cores, leading to an acellular and vulnerable plaque. We compared the morphology of the high-fat, high-cholesterol diet–induced aortic sinus lesions in Ldlr−/− and Ldlr−/−CEHTg mice. Serial sections were stained with Masson’s trichrome stain and H&E and immunostained with antibody to macrophage marker MOMA-2. Representative images in Figure 5 clearly show that the lesions from Ldlr−/− mice are largely acellular, containing large cholesterol clefts (Figure 5, A and B), while intact foam cells are present throughout the lesions from Ldlr−/−CEHTg mice (Figure 5, B and C). The quantification of acellular/necrotic area and number of macrophages and TUNEL-positive cells are shown in Table 1.

n = 9 per genotype.

In accordance with fewer lesions, cholesterol content of thoracic and abdominal aortae was low, and while the EC and FC content was lower in CEH transgenics compared with Ldlr−/− controls, this decrease did not reach statistical significance. Taken together with the en face analyses, these data demonstrate that macrophage-specific expression of CEH leads to attenuation of diet-induced atherosclerosis in Ldlr−/− mice.

**Figure 3**

Ldlr−/−CEHTg mice have reduced atherosclerosis compared with Ldlr−/− controls. Ldlr−/− and Ldlr−/−CEHTg mice were fed a Western diet for 16 weeks. Aorta (from aortic sinus to the iliac bifurcation) was isolated, opened and pinned to expose the lesions, and imaged on a black background. (A) Representative images of the aorta. The white horizontal line marks the place where the aortic arch was separated from the thoracic and abdominal aortae. (B) A magnified image of the aortic arch. (C) The quantification of the surface area occupied by the lesions in the aortic arch and the thoracic and abdominal aortae. Data (% area occupied by the lesions) are expressed as mean ± SEM for the indicated number of animals in each group. Original magnification, ×3. *P = 0.0008; **P = 0.004.
positive macrophage nuclei is shown in Figure 6. The lesions from Ldlr<sup>−/−</sup> mice were significantly more acellular/necrotic as assessed by the percent necrotic area (56.79 ± 14.45 versus 19.33 ± 11.33, \(P = 0.000004\)). Consistently, the number of macrophages per unit area of the lesion was significantly lower (21.74 ± 5.04 versus 55.87 ± 22.24, \(P = 0.0007\)). Further, of the number of macrophages present, the percent of TUNEL-positive macrophage nuclei was also significantly higher in the lesions from Ldlr<sup>−/−</sup> mice (49.48 ± 27.62 versus 13.83 ± 3.64, \(P = 0.0025\)). These data demonstrate that by enhancing intracellular CE hydrolysis and thus facilitating the removal of cholesterol, CEH overexpression prevents cell death and necrosis of lesion-associated foam cells.

Figure 4
Aortic lesions in Ldlr<sup>−/−</sup> CEHTg mice have significantly lower EC than lesions in Ldlr<sup>−/−</sup> mice fed a Western diet for 16 weeks. Aortae (from aortic sinus to the iliac bifurcation) were isolated, opened, and pinned to expose the lesions. After fixing in buffered formaldehyde for 24 hours, the aortic arch was cut along the line as shown in Figure 3 and lipids extracted from the resulting 2 pieces corresponding to the arch and the thoracic and abdominal aorta. FC and EC concentration (\(\mu\)g/mg protein) was determined as described in Methods. The concentration of total cholesterol is indicated at the top of the bars. Data are expressed as mean ± SEM (\(n = 6\)). \(^*P < 0.004\).

Figure 5
Lesions in Ldlr<sup>−/−</sup> CEHTg mice are more cellular. Hearts from Western diet–fed mice were fixed, paraffin embedded, and sectioned as described in Methods. (A) Representative aortic sinus lesion on 1 of the leaflets, stained with Masson’s Trichrome reagent. Original magnification, ×200. The lumen (L) of the aortic sinus is so marked for orientation. The red staining of the cytoplasm illustrates the highly cellular nature of the lesion in Ldlr<sup>−/−</sup> CEHTg mice. Limited blue staining in the core of the plaque indicates reduced collagen levels in the lesions of Ldlr<sup>−/−</sup> compared with Ldlr<sup>−/−</sup> CEHTg mice. (B) Magnification of the boxed areas in A. Serial sections were stained with H&E. Arrowheads mark the nuclei, arrows point to the cholesterol cleffs, and asterisks indicate foam cells. (C) A second serial section was immunostained with antibody to macrophage marker MOMA-2. Intact foam cells (asterisks) containing intracellular lipid droplets and stained brown with MOMA-2 antibody are visible throughout the lesion from Ldlr<sup>−/−</sup> CEHTg but not in lesion from Ldlr<sup>−/−</sup> mice. Original magnification, ×600 (B and C).

Figure 6
Higher FC efflux from peritoneal macrophages isolated from Ldlr<sup>−/−</sup> CEHTg mice compared with Ldlr<sup>−/−</sup>. CEH-mediated hydrolysis of intracellular CEs releases FC for efflux, and this step is considered the rate-limiting step in cholesterol efflux from lipid-laden foam cells. FC is subsequently effluxed by multiple pathways depending on the presence of appropriate exogenous cholesterol acceptors. To determine whether transgenic expression of CEH increased FC efflux from macrophages, peritoneal macrophages from Ldlr<sup>−/−</sup> and Ldlr<sup>−/−</sup> CEHTg mice on chow diet were labeled and loaded with cholesterol by incubating with AcLDL and \(^{[3]H}\)-cholesterol, and FC efflux by the various efflux pathways was monitored. Consistent with our earlier data with CEH overexpression in THP1 macrophages (14), significantly higher efflux of \(^{[3]H}\)-cholesterol was observed with macrophages isolated from Ldlr<sup>−/−</sup> CEH Tg mice by all efflux pathways, namely aqueous diffusion independent of a cellular transporter (3.04 ± 0.62 versus 5.12 ± 0.12, \(P = 0.005\)), ABCA1-mediated efflux to lipid-free ApoAI (6.38 ± 0.75 versus 11.11 ± 1.05, \(P = 0.003\)), ABCG1-mediated efflux to HDL (24.27 ± 1.5 versus 33.54 ± 0.44, \(P = 0.0004\)), and total efflux to 10% FBS (39.22 ± 2.47 versus 53.78 ± 2.07, \(P = 0.0014\)), confirming the role of CEH-mediated hydrolysis in regulating FC efflux. Further, percent efflux of FC from either cell type increased consistent with the efflux capacity of the exogenous acceptor (no acceptor < ApoAI < HDL < FBS). It should be noted that these data were obtained under optimal cellular conditions, which may not predict the efflux capacity in vivo.
To evaluate the effect of transgenic CEH expression in macrophages, we used thioglycollate-elicited peritoneal macrophages isolated from chow-fed Balb-c/C57BL/6 hybrid background. Consistent with earlier studies, there was an increase in the expression of CD36, ABCA1, and ABCG1 in response to lipid loading. However, there was no significant difference in the gene expression between macrophages from Ldlr<sup>–/–</sup> and Ldlr<sup>–/–</sup>CEHTg mice.

Increased expression of CEH in macrophages results in enhanced reverse cholesterol transport in vivo. To evaluate the effect of transgenic expression of CEH in macrophages on in vivo reverse cholesterol transport, we employed the model developed by Zhang et al. (18), except that we used mouse peritoneal macrophages isolated from Ldlr<sup>–/–</sup> or Ldlr<sup>–/–</sup>CEHTg mice instead of the J774 murine macrophage cell line. Ex vivo cholesterol-loaded and -labeled mouse peritoneal macrophages were injected into the peritoneal cavity of chow-fed C57BL/6 mice, and movement of [3H]-cholesterol to gall bladder bile and feces was determined. As shown in Figure 8, greater than 2-fold higher [3H]-cholesterol was associated with bile acids in gall bladder bile (0.17% versus 0.56% of injected, P = 0.0007) and feces (0.62% versus 1.48% of injected, P = 0.03) when mice were injected with macrophages from Ldlr<sup>–/–</sup>CEHTg mice. No significant difference was seen in biliary or fecal [3H]-cholesterol. The 2-fold higher delivery of macrophase-derived [3H]-cholesterol to gall bladder bile and feces clearly demonstrates an enhanced reverse cholesterol transport from macrophages isolated from Ldlr<sup>–/–</sup>CEHTg mice.

Figure 7
Peritoneal macrophages from CEH-transgenic mice have lower EC content. Thioglycollate-elicited peritoneal macrophages from chow-fed mice were isolated and loaded with AcLDL. After a 24-hour equilibration period, 1 set was incubated in serum-free medium (no extracellular acceptor) or in medium containing 10% FBS as the extracellular acceptor. Lipids were extracted after 24 hours and cellular FC and EC levels determined and normalized to cellular protein. Data are expressed as mean ± SD; n = 3. The percent decrease in FC and EC in the presence of extracellular acceptor is significantly higher in macrophages from Ldlr<sup>–/–</sup>CEHTg mice (*P = 0.05 and **P = 0.048) compared with the corresponding decrease in macrophages from Ldlr<sup>–/–</sup> mice.

Figure 6
Decreased necrosis/apoptosis of macrophages in lesions from Ldlr<sup>–/–</sup>CEHTg compared with Ldlr<sup>–/–</sup> mice. H&E-stained sections were used to determine the percentage of acellular area/necrotic area of the lesions (A), and the number of macrophages in the lesions (B) as well as the percentage of TUNEL-positive nuclei/total nuclei (C) were determined as described in Methods. Data are expressed as mean ± SEM for 5 mice per genotype, and 3 lesions were analyzed per animal. P = 0.00002 (A); P = 0.001 (B); P = 0.000008 (C).
The hydrolysis of the intracellular CE. The role for a neutral CEH was further characterized as a cytosolic enzyme in murine macrophages in hydrolyzing cellular CE was first described by Brown et al. (19). Unesterified cholesterol or FC, and not CE, can efflux from cells, while extracellular acceptor-mediated efflux of FC from macrophages is the mechanism by which FC is removed from macrophages to bile acids.

In order to examine the effects of increased in vivo expression of CEH on the development of atherosclerosis, we evaluated lesion formation in transgenic mice that overexpress CEH specifically in macrophages from atherosclerosis-susceptible species (22, 23), and overexpression of CEH results in enhanced mobilization of CE from cells in vitro (13, 14). In addition, decreased levels of CEH expression are observed in macrophages from atherosclerosis-susceptible species (22, 23), and overexpression of CEH in mouse macrophages leads to a reduction in diet-induced atherosclerosis in Ldlr−/− mice (Figure 3). The observed reduction in the aortic atherosclerosis by en face analyses was consistent with the biochemical analyses of the aortic lesions in that the aortic cholesterol content (CE and FC) was also significantly reduced in Ldlr−/−CEHTg mice (Figure 4).

While modification of cholesterol to enter the bile acid synthesis pathway (24) and direct secretion of cholesterol associated with ApoE secreted by macrophages (25) are 2 additional mechanisms proposed for cholesterol removal, extracellular acceptor-mediated cholesterol efflux is the major pathway for the removal of cellular cholesterol and is critical in preventing foam cell formation and development of atherosclerosis. Multiple pathways exist for the efflux of cellular FC. Efflux of FC via aqueous diffusion that is independent of a cellular transporter occurs with all cell types but is inefficient (26). ABCA1 mediates efflux of both FC and phospholipid to lipid-free ApoAI (22). ABCG1 and ABCG4 stimulate FC efflux to both smaller and larger subclasses of HDLs (HDL2, and HDL3, respectively) but not to lipid-poor ApoAI (27). SR-BI, on the other hand, mediates bidirectional movement of cholesterol and contributes to the net efflux to HDL and serum (17). Consistent with its role in catalyzing the obligatory first step (CE hydrolysis) in cholesterol efflux and reverse cholesterol transport (17), transgenic expression of CEH in macrophages from Ldlr−/−CEHTg mice led to an increase in FC efflux to exogenous lipid-free ApoAI (ABCA1-mediated) and to exogenous HDL (ABCG1-mediated). Highest efflux was obtained when 10% serum was used as the exogenous acceptor, which also contained phospholipids that act as a “sink” for effluxed FC. The data presented here show that while the FC generated by CEH-mediated hydrolysis of CE was effluxed by all known pathways without any apparent preference, the percent FC efflux increase corresponded to the relative importance of these different efflux pathways: aqueous diffusion or transporter independent<ABCA1 mediated<ABCG1 mediated<total efflux (to serum). This enhanced efflux led to a net reduction in FC and EC mass in macrophages from CEHTg mice (Figure 7) in the presence of an extracellular acceptor. Kinetic studies by Mazzone et al. have demonstrated that 90% of the FC released by CEH hydrolysis is available for efflux (as a cholesterol oxidase–accessible pool), but in the absence of an extracellular acceptor it is readily reesterified (28). This is consistent with our data showing a net reduction in macrophage CE content only in the presence of an extracellular acceptor and a significantly greater reduction in cellular CE in macrophages from CEH-transgenic mice (Figure 7).

While extracellular acceptor-mediated efflux of FC from macrophages is the mechanism by which FC is removed from macrophage foam cells, final elimination of cholesterol from the body occurs by the movement of this FC to the liver for excretion as...
bile acids or biliary cholesterol. Our data demonstrate that the movement of [3H]-cholesterol from macrophage to feces was 2-fold higher with macrophages from Ldlr−/−CEHTg mice (1.6% of injected) compared with those from Ldlr+/− mice (0.8% of injected) and that bile acids were the principal excretory form of [3H]-cholesterol. Given the equivalent cholesterol content (4.2–4.4 μg) of the injected macrophages, this increased movement would lead to increased removal of cholesterol from the body. Thus continued 2-fold higher removal of cholesterol in the feces in Ldlr−/−CEHTg mice due to increased FC efflux from macrophages may represent the underlying mechanism for the observed attenuation of diet-induced atherosclerosis in Ldlr−/−CEHTg mice.

The fact that the observed flux of cholesterol from macrophages to bile is in the form of bile acids is consistent with earlier reports demonstrating that while the HDL-associated FC is directly secreted into bile (29), the HDL-CE is efficiently coupled to bile acid synthesis (30).

Several enzymes can catalyze CE hydrolysis, namely HSL, which is primarily an adipose tissue enzyme, and CEL, a bile acid–stimulated pancreatic lipase. Earlier studies have looked for a role of these 2 enzymes in regulating macrophage CE metabolism and, subsequently, atherosclerosis. Transgenic expression of Hsl (8) paradoxically increased atherosclerosis. Since the Hsl transgene was expressed in C57BL/6 mice, a cholic acid–containing diet (cholic acid is a known inhibitor of hepatic bile acid synthesis) was used to induce atherosclerosis and FC efflux from macrophages was not monitored, the results cannot be compared with the present study. Based on the reduced atherosclerosis in Hsl-ApoAIV double transgenic mice compared with Hsl-transgenic mice (for whom atherosclerosis was still higher than ApoAIV transgenics), it was suggested that suboptimal concentration of exogenous FC acceptors was possibly the reason for increased CE in macrophages and increased atherosclerosis in Hsl-transgenic mice (31). Only a direct comparison of the efflux potential of serum from control and Hsl-transgenic mice could confirm this speculation. Using filipin staining, McGoohan and Anderson identified an intracellular pool of FC that is associated with cytoplasmic lipid droplets that would not be available for efflux (32). It is tempting to speculate that if Hsl-mediated hydrolysis releases FC, this pool of FC can be used to reduce CE content in macrophages, enhancing reverse cholesterol transport and, thereby, reduces CE accumulation in macrophages, enhances in vivo reverse cholesterol transport, and leads to an attenuation of diet-induced atherosclerosis in Ldlr−/−CEHTg mice. Further, this CEH does not share any significant sequence homology with Hsl or CEL and is a member of the carboxylesterase family. Genome-wide BLAST search of human and mouse genomes shows that while only a single gene coding for CEH is present on human chromosome 16 (CES1), the corresponding mouse chromosome 8 has at least 9 genes with greater than 95% homology to CEH. Although the enzymes coded by all these murine genes have not been characterized and their substrate specificities are not yet established, it is tempting to speculate that this redundancy may contribute in part to the inherent protection of mice from atherosclerosis. Future knock-down studies will establish the identity of one or more of these carboxylesterases in mice as bona fide murine macrophage CEH.

Earlier attempts to reduce CE accumulation in macrophages targeted the Acat-mediated FC reesterification step. Targeted disruption of Acat-1, however, led to massive xanthomatosis with little effect on atherosclerosis (33). Acat-1 deficiency also caused marked qualitative differences in atherosclerotic lesions including a lack of CE and markedly decreased macrophage content in advanced lesions due to progressive cell death from FC toxicity (34). Dove et al. showed that although Acat-1 deficiency increases cellular FC, it disrupts cholesterol efflux leading to FC-mediated toxicity (35). The data presented here shows that FC generated by increased hydrolysis of intracellular CE by CEH overexpression not only enhances FC efflux but also reduces macrophage cell death in the lesions (Figure 6). Cellular mechanisms to prevent FC toxicity include Acat-mediated FC esterification and cellular FC efflux (36). Thus strategies targeting Acat-1 inhibition as the means to reduce cellular CE content eliminate one of the major mechanisms for reducing FC toxicity. On the other hand, enhancing CEH-mediated hydrolysis of intracellular CE maintains both these pathways intact and functional and thereby does not lead to FC accumulation, as shown here and by our earlier data (13, 14). Thus a fundamental difference exists in achieving the goal of reduced cellular CE levels by Acat-1 inhibition versus CEH overexpression. The FC generated by CEH-mediated hydrolysis has 2 fates, namely reesterification by Acat-1 or efflux to extracellular acceptors. Thus while in Acat-1−/− cells excess FC cannot be reesterified, resulting in cellular toxicity and cell death, in CEH overexpressing cells, FC released by CEH-mediated hydrolysis is either effluxed or reesterified by Acat-1, resulting in no FC buildup and thus no toxicity or cell death as shown here with highly cellular lesions in Ldlr−/−CEHTg mice (Figures 5 and 6). It should be pointed out that antisense oligonucleotide–mediated inhibition of Acat-2, the isoform present in liver and intestine and not in macrophages, does reduce atherosclerosis (37), but this effect is due to changes in the plasma lipoprotein profile and has little to do with macrophage CE metabolism.

In conclusion, we have demonstrated for what we believe to be the first time that macrophage-specific expression of CEH attenuates atherosclerosis and leads to reduced accumulation of CE in the vessel wall. Our studies also indicate that CEH inhibits atherosclerosis by increasing FC efflux from macrophages and thereby promoting reverse cholesterol transport in vivo and increasing the removal of cholesterol from the body as bile acids. These studies thus provide the much needed “proof of principle” that reducing CE accumulation in macrophage foam cells by enhancing hydrolysis is antiatherogenic and identify macrophage CEH as a potentially novel target to attenuate atherogenesis.

Methods

Production and screening of transgenic mice. All animal protocols were approved by the Institutional Animal Care and Use Committee at the Virginia Commonwealth University. The human scavenger receptor (SR-A) promoter/enhancer was used to drive macrophage-specific expression of human CEH in mice. The plasmid pAL1 containing the SR-A promoter/enhancer and all the necessary elements for chimeric transgene construction (poly linker region and heterologous intron) was obtained from Christopher Glass (UCSD, La Jolla, California, USA). Full-length human CEH cDNA (~2 kb) with an infarame stop codon was cloned into the EcoRI site in the poly-linker region of the plasmid pAL1. The sequence of the chimeric transgene...
was confirmed by sequencing. The SRA-CEH chimeric transgene was sepa-
rated from the vector sequence by digestion with NotI and XhoI, purified by
agarose gel electrophoresis, and injected into the pronuclei of fertilized
mouse eggs obtained from superovulated female mice (C57BL/6 or Balb/c-
C57BL/6 hybrids). The injected eggs were surgically transferred to ovi-
ducts of surrogate females. Offspring were screened for integration of
the transgene by PCR amplification of the tail DNA with the upstream primer
sequence 5′-ATGGCAAATGGCTGGGAAGTTC-3′ and the downstream
primer sequence 5′-TTTCCAAGAAGAAGATTGGAATC-3′ to yield a 681-
bp product corresponding to the nucleotide sequence between residues 133
and 792 of human macrophage CEH cDNA. The transgenic founder lines
were maintained and propagated. To evaluate the role of CEH in the devel-
opment of atherosclerosis, CEH-transgenic mice were crossed with ather-
erosclerosis-susceptible Ldlr–/– mice that had a C57BL/6 background (The
Jackson Laboratory). All animals were genotyped for CEH and LDLR. Two
upstream primers were used, 5′-AGGACAGCCATGGTCTGTGTG-3′
(83–105 bp of the Neo cassette) and 5′-TGTTGATGAGACGAAGATT-
GC-3′ (380–402 bp of mouse LDLR), along with one downstream primer,
5′-CAGTGTCTTCTATCATGTTG-3′ (673–695 bp of mouse LDLR), to
yield a single PCR product of 500 bp and 316 bp with Ldlr+/– and Ldlr+/–
genotypes, respectively. Both products were obtained with heterozygous
LDLR+/– mice. Littermates with or without CEHTg in Ldlr+/– background
(Ldlr+/–CEHTg and Ldlr+/– mice) were included in the studies.

Measurement of CEH expression. Mice were injected intra-peritoneally
with 4% thio-glycollate solution, and macrophages were harvested 4 days
later by lavage of the peritoneal cavity. The peritoneal macrophages
were resuspended in RPMI containing 10% fetal bovine serum. Total RNA
from adherent cells was extracted after 24 hours using RNeasy kit (QiAGEN).
Liver, lung, spleen, kidney, and heart were also harvested and total RNA
extracted using TriReagent (Molecular Research Center). The expression
profile of CEH was determined by real time PCR, and CEH mRNA copy
number in each tissue per unit of total RNA was calculated using a stan-
dard curve as described in ref. 38. CEH activity in adherent macrophages
was determined using the radiometric assay (39).

Total plasma cholesterol and cholesterol distribution among plasma lipoproteins.
A modified column lipoprotein profile method was used (40). Whole
plasma aliquots frozen and stored at −80°C were thawed at 4°C. Total
plasma cholesterol concentration was determined by a microenzymatic
method. Approximately 20 μg of cholesterol was injected onto an FPLC
system (Superose 6 HR 10/30 column; Amersham Biosciences) with online
mixing of the column effluent with enzymatic reagent (Cholesterol Liquid
Stable; Thermo Electron) for acquiring lipoprotein cholesterol profiles.
The output generated is in millivolts. The data were acquired on a personal
computer running ChromPerfect Spirit chromatography software (Justice
Software). The system was optimized so that the area under the profiles
was proportional to the cholesterol mass. Area percent in each lipoprotein
fraction, VLDL, LDL, and HDL was applied to total plasma cholesterol to
calculate cholesterol concentration in the lipoprotein fractions.

Quantitative atherosclerotic analyses. Male and female littermates with or
without CEHTg in Ldlr+/– background (Ldlr+/– CEHTg and Ldlr+/–) were
included in the study at 10 weeks of age. The total number of animals in
each group was therefore determined by the availability of the correct geno-
type and gender within a litter. Mice were fed a Western-type high-fat, high-
cholesterol diet (TD88137; Harlan Teklad), which contained 21% fat, 0.15%
cholesterol, and 19.5% casein by weight with no sodium cholate. Animals
were weighed every 2 weeks, and after 16 weeks nonfasting plasma was
collected. The aorta was dissected from the heart to the iliac bifurcation,
cleaned of any surrounding tissue, opened longitudinally, pinned on black
wax, and fixed for 24 hours in 10% buffered formalin. The fixed aortae were
imaged on a black background using a Canon digital camera fitted with a
60-mm, f/2.8 Macro Lens. Total area and the area occupied by the lesions
in the aortic arch and thoracic and abdominal aortae was determined using
BIOQUANT Image Analysis 98 software. The person quantifying the area
occupied by lesions was blinded to the identity of the images. Extreme
care was taken to ensure that any residual adventitial fat that appeared
translucent on the images was not included in the area occupied by the
lesions that were dense and opaque. For determination of EC mass of the
lesions, the aorta was cut into 2 pieces, the aortic arch and the thoracic
and abdominal aortae, along the line shown in Figure 3, and FC and EC masses
were determined in these 2 pieces as previously described (41). Briefly,
lipids were extracted in 2:1 chloroform/methanol with 0.5% cholestaed added
as an internal standard, and FC and total cholesterol (after saponification)
were measured by gas-liquid chromatography. EC mass was determined as
the difference between total cholesterol and FC. The delipidated tissue
protein was then digested and dissolved in 1N NaOH, and total protein
was determined (42). Data (μg cholesterol/mg total protein) are expressed
as mean ± SD for 6 animals per genotype.

Morphological analyses of the lesions. Hearts from mice fed a high-fat, high-
cholesterol diet were fixed in buffered formalin, paraffin embedded, and
sectioned. Once the aortic sinus was visible, 3–4 serial sections (4 μm thick)
were transferred to numbered slides. Consequently, numbered slides were
then stained with Masson’s Trichrome stain and H&E and immunostained
with antibody to macrophage marker MOMA-2 (43) or stained to deter-
mine the TUNEL-positive macrophages using the In Situ Cell Death Detec-
tion Kit, POD (Roche). Images were acquired using an Olympus inverted
microscope fitted with a digital camera at the magnifications indicated in
the figure legends. Images of the H&E-stained sections were used to deter-
mine the total acellular area of the lesion using the BIOQUANT software.
This area is expressed as a percentage of the total lesion area. Total num-
ber of macrophages were counted in 3 fields (300 × 420 μm) per section,
and the mean ± SD was determined for 5 mice per genotype and 3 lesions
per animal. Total number of nuclei as well as TUNEL-positive nuclei
were determined from serial sections, and data are expressed as percent
TUNEL-positive nuclei.

Cholesterol efflux from peritoneal macrophages. Thioglycolate-elicted macro-
phages from chow-fed animals were plated in 12-well tissue culture plates
in RPMI supplemented with 10% FBS. Nonadherent cells were removed
after 24 hours, and the intracellular FC and EC pools were labeled with
[3H]-cholesterol and FC for 24 hours. Similar distributions of radioactivity
in FC (54.3 ± 5.5% in Ldlr–/– versus 59.7 ± 2.1% in Ldlr–/– CEHTg) and EC
(45.7 ± 5.5% in Ldlr–/– versus 40.3% ± 2.1% in Ldlr–/– CEHTg) were observed
in macrophages from either genotype following 24-hour equilibration. FC
eflux to ApoA1, HDL, and 10% FBS was determined as described previously
(14). Cholesterol efflux experiments were performed in duplicate, and the
data (μg efflux per 100 mg of HDL) are expressed as mean ± SD for 3 animals
per genotype.

Gene expression in peritoneal macrophages. Thioglycolate-elicted macroph-
ages were isolated from Ldlr–/– and Ldlr–/– CEHTg mice. Cells were plated
in 60-mm tissue culture dishes and nonadherent cells removed after 24
hours. One set of cells was loaded using ACDL (25 mg/ml) for 48 hours.
Total RNA was extracted from nonloaded and loaded cells using RNeasy
Kit (QiAGEN) and expression of Abca1, Abcg1, Cd36, Mar1, Scarb1, and CEH
determined by real time RT-PCR as described previously (35). The level of
expression for each gene in ACDL-loaded cells was normalized to the cor-
responding levels in nonloaded cells.

Measurement of cholesterol from macrophages to bile and feces in vitro. For
[3H]-cholesterol labeling and cholesterol loading, thioglycolate-elicted macrophages
were isolated from Ldlr–/– and Ldlr–/– CEHTg mice. Cells from 4 mice were pooled and plated in 100-mm petri dishes. After 4 hours, nonadherent cells were removed and adherent cells were radiolabeled with
5 μCi/ml [3H]-cholesterol and cholesterol enriched with 50 μg/ml of
AcLDL for 24 hours (18). These foam cells were equilibrated in serum-free medium with 0.2% bovine serum albumin for 24 hours. Cells were exposed to MEM containing no calcium or magnesium and then detached using the same medium supplemented with 20 mM EDTA. Cells were collected by repeated pipetting, spun down, and resuspended in RPMI medium immediately before use. The distribution of [3H]-cholesterol measured by TLC (64%-68% in CE) and cholesterol mass measured by GLC (63%-67% in CE) between FC and CE were very similar between macrophages from both genotypes. On average, the cell suspension contained 2 \times 10^6 cells/ml at 1.5 \times 10^6 dpm/ml and total cellular cholesterol of 4.3 \mu g.

In vivo studies, wild-type C57BL/6 mice (The Jackson Laboratory) maintained on chow diet were injected intraperitoneally with cholesterol-loaded and [3H]-cholesterol–labeled foam cells from either Ldlr-/- or Ldlr-/- CEHTg mice (0.5 ml) and transferred to metabolic cages. Feces were collected from 0 to 48 hours and stored at -20°C prior to lipid extraction. At 48 hours, mice were euthanized and gall bladder bile was collected.

For lipid extractions, biliary cholesterol and bile acids were extracted as described by Batta et al. (45). Values are expressed as a percent of total injected [3H]-cholesterol as described by Moore et al. (46).

Statistics. Results were analyzed by 2-tailed Student’s t test with the use of GraphPad Prism version 4 software, which tests for normality before running the Student’s t test. While statistical significance for all comparisons was assigned at P < 0.05, the individual P values are included in the text.

Acknowledgments
This work was supported by research grant (HL-069946) from National Heart, Lung, and Blood Institute to S. Ghosh. The authors thank Christopher Glass for providing the pAL1 vector. The transgenic mice were developed in the Institutional Massey Cancer Center Transgenic/Knock-out Mouse Core facility supported in part by a grant (P30 CA16059) from NCI. We thank Daniel Radar, Jeffrey Billheimer, and George Rothblat for providing the protocol used for measuring in vivo reverse cholesterol transport using mouse peritoneal macrophages and Rajendra Tangirala for advice on the morphological analyses of sinus lesions.

Received for publication September 27, 2006, and accepted in revised form June 26, 2007.
