CYP3A inducers and drug interactions

In the 1960s, it was shown that repeated administration of “catatoxic” steroids to rodents conferred resistance against the harmful or anesthetic effects of structurally unrelated drugs (reviewed in ref. 1). For example, rats treated for several days with the anti-mineralocorticoid spironolactone were almost completely protected against otherwise fatal doses of the cardiac toxin digitoxin. Among the most potent of these catatoxic steroids was pregnenolone-α-carbonitrile (PCN). It was subsequently shown that PCN and other catatoxic steroids mediate their protective effects by inducing the transcription of hepatic oxygenases, including cytochrome P450 3A oxygenase (CYP3A), which metabolizes most prescription drugs. In an interesting twist, CYP3A induction was also shown to cause an important class of dangerous drug-drug interactions wherein the inducing drug accelerates the metabolism of other drugs that are CYP3A substrates (reviewed in refs. 2, 3).

At the time, the molecular basis for CYP3A induction was unknown; however, it was clear that the potential mechanism would have to account for two puzzling observations. First, there was a remarkable structural diversity among known chemical inducers of CYP3A, which included compounds as big as the macrocyclic antibiotic rifampicin (MW > 800) and, paradoxically, both nuclear receptor agonists and antagonists. Second, there were pronounced differences among species in CYP3A induction responses. For example, PCN robustly induces CYP3A in rodent but not human hepatocytes. Conversely, rifampicin induces CYP3A in human but not rodent hepatocytes. Studies with CYP3A promoter sequences and hepatocytes derived from different species showed that these species-specific differences were a consequence of host cell factors rather than differences in CYP3A promoters (reviewed in ref. 3). It appeared as though the mechanism underlying CYP3A induction was likely to be complex and involve multiple receptors.

PXR: a promiscuous xenobiotic receptor

The 1990s were an exciting time in the orphan nuclear receptor field, with ligands identified for retinoid X receptors (RXRs), PPARs, liver X receptors (LXRs), and farnesoid X receptor (FXR) (reviewed in refs. 4, 5). In 1997, our nuclear receptor drug discovery group at Glaxo Wellcome (now GlaxoSmithKline) came across an expressed sequence tag that encoded part of a novel nuclear receptor. We went on to clone this receptor and show that it was abundantly expressed in the liver. As part of our group’s ongoing campaign to identify ligands for orphan nuclear receptors, we screened the receptor against a large library of compounds. Among our initial hits was PCN, which bound and activated the receptor at concentrations that were consistent with that required for CYP3A induction. We named this protein the pregnane X receptor (PXR) based on the efficient activation of the receptor by PCN and other natural and synthetic C21 steroids (pregnanes). We further demonstrated that PXR acted through a DNA response element located within the rodent Cyp3a gene promoter (6).

While we had identified the long-sought-after PCN receptor, this work did not address the broader issue of the overall contribution of PXR to CYP3A induction and drug-drug interactions. This work did set the stage for our 1998 study published in the JCI, in which we cloned and characterized the human ortholog of PXR (7), which was subsequently reported by two other groups and referred to as steroid and xenobiotic receptor (SXR) (8) and PAR (9), respectively. The DNA-binding domain of mouse and human PXR shares 96% amino acid identity, and both orthologs bind the same response elements within CYP3A promoters. However, the ligand-binding domains are only 76% identical, which is much lower than the identity between orthologs of other nuclear receptors. This divergence provided the first hint that mouse and human PXR may have distinct pharmacologic activation profiles.

In cell-based reporter assays, human PXR was activated by a structurally diverse set of established CYP3A inducers, including the drugs rifampicin, dexamethasone, RU486, spironolactone, cyproterone acetate, clotrimazole, and lovastatin. Importantly, there were striking differences in

Thus, PXR assays are also useful for assessing the potential of unregulated remedies to interact with prescription drugs.

In closing, our *JCI* paper identified PXR as a molecular basis for drug-drug interactions and introduced the concept of a nuclear receptor acting as a generalized xenobiotic sensor. Ironically, while our nuclear receptor group at Glaxo Wellcome set out to identify new drug targets, our pharmaceutical legacy is the discovery of an important anti-target!
